9. CHARACTERISTICS OF VTOL-STOL AIRCRAFT

The interest in a wide variety of aircraft having VTOL-STOL capability has created the need for establishing preliminary-design methods for the prediction of the aerodynamic characteristics of such vehicles.

The terms VTOL, STOL, and V/STOL appear many times in the literature. VTOL means "vertical take-off and landing." STOL means "short take-off and landing," and vehicles of this classification do not have vertical take-off and landing capability. V/STOL means the capability to perform both vertical and short take-offs and landings. The many ways of achieving VTOL-STOL capability are exhibited in the proposed and existing vehicles of this family. There are four basic VTOL-STOL principles involved for accomplishing the conversion from hovering to cruise flight; namely, aircraft tilting, thrust tilting, thrust deflection, and dual-propulsion. These four conversion principles are coupled with four different propulsion methods; namely, rotor, propeller, fan, and jet, to give the family of basic V/STOL types. In the broad sense the material presented in this section does not include all V/STOL concepts. Specifically, the methods presented in Section 9 are applicable to predicting the forces and moments on free propellers (Section 9.1), power-on lift and drag forces of propeller-wing combinations (Section 9.2), and the forces and moments on isolated ducted propellers as functions of power and angle of attack (Section 9.3). No discussion or methodology is presented for rotor-type V/STOL aircraft. In addition to the material presented in this section, there are additional methods pertaining to STOL aircraft given in Section 6. Specifically, these methods pertain to jet-flap configurations; i.e., both internally-blown flaps (IBF) and externally-blown flaps (EBF).

Because of the unusual low-speed configurations and the effects of power and high angles of attack in the low-speed flight regime, which are typical of VTOL-STOL vehicles, conventional methods of predicting aerodynamic characteristics at low speeds are not applicable in most cases. In cruise flight, VTOL-STOL vehicles can usually be analyzed by conventional methods. Therefore, the primary problem is the prediction of characteristics that exist as a result of high-velocity slipstreams, high angles of attack, and geometry variations in the hover and transition flight regimes.

Because of the scope of VTOL-STOL aerodynamics and the scarcity of verified theoretical methods and design charts, a literature summary is presented as Table 9-A, accompanied by a subject index on page 9-34, a "key" to the summary table on page 9-35, and a bibliography on pages 9-3 through 9-33.

V/STOL aircraft are characterized by the following four basic and unique characteristics:

1. High power requirements in hover and transition
2. High-velocity slipstreams in hover and transition
3. Inherent deficiencies in aerodynamic stability and control in hover and low-speed flight
4. Special provisions for performing the conversion from the hovering to the cruise configuration

The high power required in hovering and transition is not of primary concern to the stability and control engineer and is not considered in the Datcom. However, it should be noted that the engine-operation problems are extremely significant in the design of a V/STOL vehicle. The high power required in hovering and transition results in both higher fuel consumption and greater noise.

The magnitude of these increases depends on the type of propulsion system used. Both fuel consumption and noise level progressively increase from the rotor to the propeller, the fan, and the jet.

The high-velocity slipstream required in hovering and transition flight introduces problems due to surface erosion, recirculation of dust and debris, ingestion of foreign objects, and slipstream recirculation, which can result in adverse aerodynamic effects and ingestion of hot gases into the engine, resulting in a serious reduction in engine thrust. Only the aerodynamic effects of the slipstream are considered in this section. Slipstream recirculation can affect the pressure on the airframe, which can cause significant changes in the vertical lift. When a single high-velocity slipstream exhausts in still air, suctions are generated on the surrounding surface because of the entrainment into the high-velocity slipstream. This "suckdown" effect is a pressure reduction and reduces the vertical lift. This lift loss is evident during hovering near the ground for a configuration with a single vertical slipstream or a close cluster of vertical slipstreams. On the other hand, when several vertical slipstreams are dispersed over the planform, the high-velocity slipstreams tend to meet on the ground between the exits, and the consequent upflow can produce positive-pressure regions between the exits to counterbalance the "suckdown" generated by the entrainment. Unfortunately, this upward flow of air is not very steady or symmetrical and can result in random upsetting motions. In addition, for configurations with a tail behind the slipstreams, additional interference effects on longitudinal trim and stability can occur during transition flight. (Strong downwash and sidewash fields can develop in the region aft of the exits as a result of the rearward deflection and distortion of the slipstreams together with the entrainment of the free-stream flow.) References pertaining to the aerodynamic effects of high-velocity slipstreams are listed under one or more of the following specialized categories in table 9-A:

5.5 Ground Effects

5.10 Jet-Wake or Propeller-Slipstream Effects

5.11 Jet-Induced Effects

An important aspect of V/STOL hovering and low-speed flight is the inherently low level of aerodynamic stability and control. Aerodynamic control and static and dynamic stability vary with dynamic pressure in the free stream, and they all drop off rapidly as the flight speed is decreased. In hovering there is no aerodynamic control effectiveness (unless the control surface is in a high-velocity slipstream), and it is usually necessary to provide an additional control system for hovering and low-speed flight. In hovering flight the static stability is neutral (no stability of attitude) for all V/STOL types. The dynamic stability in hover is about neutral for jet-V/STOL types, but other types are usually dynamically unstable in the form of unstable pitching and rolling oscillations. Almost any system that will provide control for the pilot under these conditions can also be used to augment stability. However, the way in which this should be accomplished has not been clearly settled for any V/STOL type. The cost, complexity, reliability, and maintainability of any augmentation system must be weighed against the improvements in handling qualities and the potential reductions in control requirements. The problem immediately becomes more complex, since there is still a great deal of controversy regarding control-system requirements and handling-quality criteria. References pertaining to the aerodynamic stability and control deficiencies in hovering and low-speed flight may be found under one or more of the following specialized categories in table 9-A:

5.1 General Static Stability and Control

5.2 Dynamic Stability

5.3 Handling Criteria

5.4 Handling Qualities

5.7 Stabilization

5.8 Zero or Low-Airspeed Control and/or Control Systems

Although wind-tunnel tests cover a wide variety of V/STOL configurations, they are often of questionable accuracy because of wall interference effects and/or data-accuracy limitations at the low tunnel velocities required to simulate low-speed flight. Large flow-deflection angles are required for flight at very low speeds, and when these conditions are duplicated by a powered model in a wind tunnel, the presence of the tunnel walls have a first-order effect on tunnel flow conditions. Most existing low-speed wind tunnels are inadequate for the simulation of powered-lift low-speed flight because of their size limitations. The test section must be large compared to model dimensions to minimize the adverse effects of the wind-tunnel walls on the flow field. Simply testing models of smaller scale in an effort to avoid wall-interference effects often has not proved satisfactory, because of the significant errors in test data associated with low Reynolds number and the problems encountered in the design and manufacture of a powered model to a small scale. There appears to be a limit, which is a function of the tunnel test-section size and shape, model size, flow deflection angle, and model configuration, at which the tunnel-wall constraint causes a complete flow breakdown. The effects of all these variables on the accuracy of the wind-tunnel data are quite complex and some are not yet clearly understood. However, one fact has become very clear, and that is that most existing wind tunnels are simply too small for simulation of V/STOL flight.* References pertaining to wind-tunnel test techniques are listed under category 5.12 in table 9-A.

VTOL-STOL SUBJECT INDEX

1. Propeller-Driven Aircraft and Component Combinations

    1.1 Boundary-Layer Control
    1.2 Tilting Wing
    1.3 Deflected Slipstream
    1.4 Ducted Propeller
    1.5 Tilting Propeller
    1.6 Tailsitter

2. Jet-Driven Aircraft and Component Combinations

    2.1 Deflected Jet (Vectored Jet)
    2.2 Lift Plus Propulsion
    2.3 Tailsitter
    2.4 Tilting Engine
    2.5 Boundary-Layer Control

3. Fan-Driven (Lifting System) Aircraft and Component Combinations

    3.1 Fan in Wing
    3.2 Fan in Fuselage

4. Individual Components

    4.1 Free Propeller
    4.2 Ducted Propeller
    4.3 Plane Wing
    4.4 Annular Wing
    4.5 Jet Flaps or Jet-Augmented Flaps

5. Specialized Categories

    5.1 General Static Stability and Control
    5.2 Dynamic Stability
    5.3 Handling Criteria
    5.4 Handling Qualities
    5.5 Ground Effects
    5.6 Gyroscopic Effects
    5.7 Stabilization
    5.8 Zero or Low-Airspeed Control and/or Control Systems
    5.9 Propeller-Rotation-Direction Effects
    5.10 Jet-Wake or Propeller-Slipstream Effects
    5.11 Jet-Induced Effects
    5.12 Wind-Tunnel Test Techniques
    5.13 Miscellaneous Effects

6. Bibliographies and Compilations

KEY TO VTOL-STOL SUMMARY TABLE

Column Heading	Abbreviation	Definition
V/STOL Concept	BLC	Boundary-Layer Control
	DJ	Deflected Jet (Vectored Jet)
	DP	Ducted Propeller
	DSS	Deflected Slipstream
	FIF	Fan in Fuselage
	FIW	Fan in Wing
	FP	Free Propeller
	HL	High Lift (Flaps, Slots, Slats)
	JF	Jet Flap or Jet-Augmented Flap
	L+P	Lift-Plus-Propulsion Engine
	RF	Rotating Flap

9.1 FREE-PROPELLER CHARACTERISTICS

The methods of this Section are for estimating forces and moments on propellers. The primary purpose of this work is to provide information for analysis of direct propeller effects during the transition flight phase of V/STOL aircraft.

Operation of a propeller in an unsymmetrical flow field results in unsymmetrical loading on the blades as a function of their rotational position, which, in turn, produces forces normal to the thrust axis resulting in pitching and yawing moments. Flow field asymmetries result from either thrust-axis tilt or from flow angles induced by the airplane lifting surfaces. The propellers on V/STOL aircraft will encounter greater asymmetries than those of conventional aircraft because of the greater thrust-axis tilt and greater induced upwash of more effective high-lift devices.

Methods for the prediction of forces and moments on propellers inclined with respect to the free stream are developed by DeYoung in reference 1. DeYoung has generalized existing small-incidence theory (references 2 and 3) using a propeller solidity based on average blade chord. Simple expressions are thus developed for propeller normal (or side) force and some of the principal derivatives. DeYoung develops these expressions by first determining approximate equations of propeller geometry and operating parameters from the theory presented by Ribner in references 2 and 3, and then establishing by statistical means the equation constants and slightly altered functions from computed data of given blade shapes.

DeYoung also derives expressions for the ratio of normal force at high incidence to normal-force derivative at zero incidence, and the ratios of thrust, torque, and power at high incidence to the zero-incidence values.

Reference 5 presents results of a propeller test for three full-scale propellers of different design at nine angles of incidence ranging from 0 to 85 degrees. The operating conditions were selected to simulate the take-off, landing, and transition regimes of V/STOL aircraft. From the data of this reference certain generalizations can be made regarding propeller characteristics likely to be encountered in transition flight. It is shown that the thrust coefficients for given values of blade angle and advance ratio are nearly constant over a large range of thrust-axis angles of attack and that this range decreases with increasing advance ratio. Furthermore, it is shown that, over the same range of thrust-axis angles, the variations of propeller normal force and pitching moment are nearly linear. Using these generalizations it is possible to present approximate methods for the estimation of propeller forces and moments at large angles of inclination from experimental data at small angles of inclination for certain transition programs.

A general notation list is included in this Section for all free-propeller Sections.

The positive direction of forces and moments is shown in figure 9.1-4.

Notation List

A	wing aspect ratio
a_o	blade section lift-curve slope, per rad
B	number of blades

Notation List (continued)

b'	propeller blade chord, ft
$\bar{b}'$	average blade chord, ft
$b'_{.25,\ .50,}$	blade chord at $\frac{r}{R} = .25,\ .50,\ \cdots$, ft
C_N'	normal-force coefficient based on free-stream velocity and propeller disk area, $\frac{N}{q_\infty\ S_p}$
C_N	normal-force coefficient, $\frac{N}{\rho\, n^2\ D^4} = \frac{\pi J^2}{8}\ C_N'$
C_T	thrust coefficient, $\frac{T}{\rho\, n^2\ D^4} = \frac{\pi J^2}{8}\ T_c$
c_r	wing root chord, ft
D	propeller diameter, ft
J	advance ratio, $\frac{V_\infty}{nD}$
J'	modified advance ratio, $J \cos \alpha$
J_{o_T}	advance ratio at zero thrust
J_{o_P}	advance ratio at zero power
N	propeller normal force, lb
n	propeller rotational speed, rps
q_∞	free-stream dynamic pressure, lb/sq ft
R	propeller radius, ft
R_{fus}	maximum fuselage radius forward of propeller plane
r	radial distance to blade element, ft
S_p	propeller disk area, $\frac{\pi}{4}\ D^2$, sq ft
T	propeller thrust, lb
T_c	thrust coefficient based on free-stream velocity and propeller disk area, $\frac{T}{q_\infty\ S_p} = \frac{8}{\pi J^2}\ C_T$
x	longitudinal coordinate measured positive forward from wing leading edge, ft
y	lateral coordinate measured positive to right of plane of symmetry, f
Δy	lateral distance from thrust axis of one propeller blade to element of another, ft

Notation List (continued)

V_∞	free-stream velocity, ft/sec
α	wing angle of attack measured from zero lift, deg
α_{in}	inflow angle at propeller disk, deg
β	blade angle at .75R blade station, deg
$\epsilon_{z_{slip}}$	upwash induced by propeller slipstream, positive downward, deg
σ	propeller solidity, ratio of blade element area to annulus area at .75R
σ_e	effective propeller solidity (propeller solidity based on average blade chord)
δ_f	force phase angle, deg

Subscripts

α_{in}	differentiation with respect to inflow angle, α_{in}
$L_{.75}$	left blade position at three-quarters radius point
$R_{.75}$	right blade position at three-quarters radius point
fus	fuselage

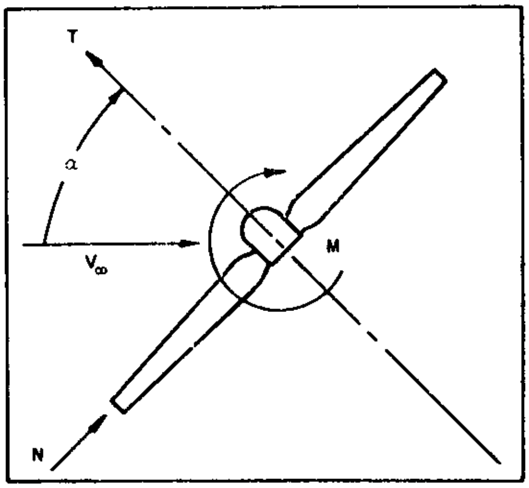

FIGURE 9.1-4 CONVENTIONS USED TO DEFINE POSITIVE SENSE OF FORCES AND MOMENTS

9.1.1 PROPELLER THRUST VARIATION WITH ANGLE OF ATTACK

Two methods are presented in this Section for estimating the thrust of a propeller at high angles of incidence. The first method is that of reference 1 and provides thrust relative to the zero-incidence value. This ratio is approximately proportional to the square of the tangent of the angle of incidence with a constant advance ratio, determined from the velocity normal to the propeller disk. In the theory the thrust is represented by the phase-angle change of the resultant velocity at the blade and takes into account both the angle-of-attack changes and the dynamic-pressure changes. A 90-degree incidence level is formulated from helicopter theory to provide a relatively small correction to the propeller theory. This thrust ratio is dependent on blade angle and advance ratio but, except for a small dependence on solidity, is independent of propeller geometry.

In the absence of complete data on a particular propeller, a second method is given that can be used to approximate the thrust at large incidence angles from experimental data at small incidence angles. This approach is formulated in reference 2, wherein it is demonstrated that certain VTOL transition programs can lie within the region of linear slope of the propeller forces and moments.

The methods presented herein are for an isolated propeller where the thrust-axis angle of attack is the angle between the free-stream velocity and the propeller thrust axis. For airplane installations this angle is often affected by flow induced by the wing, fuselage, and other propellers; however, the results of references 3 and 4 indicate that the major effects of induced flow on propeller thrust occur under conditions that are not likely to be of practical interest (high forward speed at high angles of attack).

DATCOM METHODS

Method 1

The variation of propeller thrust with angle of attack is given relative to the value at zero angle of attack, provided equal advance ratios exist as determined from the velocity normal to the propeller disk. This thrust ratio is given in reference 1 as

$$\frac{C_T\ (\alpha,J')}{C_T\ (0,J')} = 1 + \frac{3\left(\frac{J'}{J_{0_T}}\right)^2}{4\left(1 - \frac{J'}{J_{0_T}}\right)} \sin(\beta + 5) \Bigg[\tan\ (\beta + 5) + \sigma_e \left(1 + \sqrt{1 + \frac{2}{\sigma_e} \tan\ (\beta + 5)}\right)(1 - \cos\alpha)\Bigg] \tan^2\alpha \qquad \text{9.1.1-a}$$

where all parameters are defined in the general notation list of Section 9.1 and the positive direction of forces and angles is shown in figure 9.1-4.

The procedure to be followed in evaluating equation 9.1.1-a is outlined in the following steps.

Step 1. Determine the propeller effective solidity σ_e by

$$\sigma_e = \frac{\bar{b}'}{b'_{.75}} \sigma = \frac{4B\bar{b}'}{3\pi D} \qquad 9.1.1\text{-b}$$

where

$\bar{b}' = \frac{1}{0.8} \int_{.2}^{1} b' \, dx'$, which may be approximated by

$$\bar{b}' = 0.16 \left(\frac{5}{4} b'_{.25} + 2b'_{.50} \; ' \; 2b'_{.75} + b'_{.95} \right) \qquad 9.1.1\text{-c}$$

$b'_{.25,\ .50,\ldots}$ are obtained from the propeller blade planform curve at $\frac{r}{R} = 0.25,\ 0.50, \ldots$

Step 2. The advance ratio at zero-thrust J_{O_T} is obtained from figure 9.1.1-7 as a function of β. This functional relationship is given in reference 1 as

$$J_{O_T} = 2.2 \tan(\beta + 5) \qquad 9.1.1\text{-d}$$

Step 3. Using equation 9.1.1-a obtain $\frac{C_T\ (\alpha, J')}{C_T\ (0, J')}$ with the σ_e and J_{O_T} values obtained in Steps 1 and 2. With this result values of the thrust ratio can be computed for a range of angles of attack and modified advance ratios.

Step 4. Determine the propeller thrust coefficient at selected angles of attack and modified advance ratios by

$$C_T(\alpha, J') = \frac{C_T\ (\alpha, J')}{C_T\ (0, J')} C_T\ (0, J')$$

where $C_T(0, J')$ is the propeller thrust coefficient at zero angle of attack, but with the velocity equal to $V_\infty \cos \alpha$. This parameter will normally be a known quantity.

Figures 9.1.1-8a-g and 9.1.1-11a-d present a comparison of experimental data from reference 2 with the Datcom method as computed from equation 9.1.1-a.

Method 2

This method is suggested in reference 2 for estimating propeller thrust at high angles of attack when experimental data at zero angle of attack are available.

The experimental data of reference 2 show that the thrust coefficient for given values of blade angle and advance ratio is practically constant over a wide angle-of-attack range at low advance ratios, and that this range diminishes with increasing advance ratio. Using these observations, it is possible to identify these ranges in VTOL transition programs.

The boundary of this region, presented in figure 9.1.1-13, has been determined on the basis of five-percent thrust-coefficient increases from the zero-angle-of-attack values for two propellers at a constant blade angle, tested in reference 2. The region varies with blade angle. The boundary curve of figure 9.1.1-13 is defined for a 12-degree blade angle, typical for maximum propeller efficiency in very low-speed flight. The characteristics of the two test propellers are presented in table 9.1.1-A.

As a simple rule of thumb, the propeller thrust at high angles of attack may be assumed to equal the value at zero angle of attack if the modified advance ratio falls below the boundary of figure 9.1.1-13.

A 1-g transition program for a hypothetical airplane described in reference 3 is also shown in figure 9.1.1-13. This program is based on the data obtained for propeller 1 of reference 2. The modified advance ratio lies well below the boundary curve. However, for conditions of steep descent or rapidly decelerating transition the boundary could be exceeded.

Sample Problem

Method 1

Given: The three-bladed propeller designated as propeller number 1 of reference 2. The following example is based on four values of the modified advance ratio over a thrust-axis angle-of-attack range from 0 to 85°.

$B = 3$ $\qquad$ $D = 12$ ft $\qquad$ $\beta = 12^{\circ}$

r/R	0.25	0.50	0.75	0.95
b',ft	0.89	1.115	1.175	1.18

J'	0.1	0.2	0.4	0.6
$C_T(0,J')$	0.132	0.121	0.083	0.032

Compute:

Step 1. Determine the effective propeller solidity σ_e.

$$\bar{b}' = 0.16\left[\frac{5}{4}b'_{.25} + 2b'_{.50} + 2b'_{.75} + b'_{.95}\right] \quad \text{(equation 9.1.1-c)}$$

$$= 0.16\left[\frac{5}{4}(0.89) + (2)(1.115) + (2)(1.175) + 1.18\right]$$

$$= 0.16\,(6.87) = 1.10$$

$$\sigma_e = \frac{4B\bar{b}'}{3\pi D} = \frac{(4)(3)(1.10)}{(3)(12)\pi} = 0.117 \qquad \text{(equation 9.1.1-b)}$$

Step 2. Determine the advance ratio at zero-thrust J_{0_T} from figure 9.1.1-7 at $\beta = 12^\circ$.

$$J_{0_T} = 0.6725$$

Solution:

Determine the ratio of the thrust coefficient at inclination to the thrust coefficient at zero angle of incidence.

$$\begin{aligned}
\frac{C_T(\alpha, J')}{C_T(0, J')} &= 1 + \frac{3\left(\frac{J'}{J_{0_T}}\right)^2}{4\left(1 - \frac{J'}{J_{0_T}}\right)} \sin(\beta + 5) \Big| \tan(\beta + 5) \\
&\quad + \sigma_e \left(1 + \sqrt{1 + \frac{2}{\sigma_e} \tan(\beta + 5)}\right)(1 - \cos\alpha) \Big| \tan^2\alpha
\end{aligned}$$

(equation 9.1.1-a)

$$\begin{aligned}
&= 1 + \frac{3\left(\frac{J'}{0.6725}\right)^2}{4\left(1 - \frac{J'}{0.6725}\right)} \sin(17) \Big| \tan(17) \\
&\quad + 0.117\left(1 + \sqrt{1 + \frac{2}{0.117} \tan(17)}\right)(1 - \cos\alpha) \Big| \tan^2\alpha \\
&= 1 + \frac{6.64\, J'^2}{4 - 5.95J'} (0.2924) \Big| 0.3057 + 0.409(1 - \cos\alpha) \Big| \tan^2\alpha \\
&= 1 + \frac{1.939J'^2}{4 - 5.95J'} \Big| 0.3057 + 0.409\,(1 - \cos\alpha) \Big| \tan^2\alpha
\end{aligned}$$

Using this result obtain $\frac{C_T(\alpha, J')}{C_T(0, J')}$ as a function of J' and α. This is calculated below for seven angles of attack. Note that at $J' = 0$, $\frac{C_T(\alpha, J')}{C_T(0, J')} = 1.0$; and at $J' = J_{0_T}$, $\frac{C_T(\alpha, J')}{C_T(0, J')} \longrightarrow \infty$

①	②	③	④	$\left[C_T(\alpha,J')/C_T(0,J')\right]-1$						
				α=85°	79.5°	75°	67.5°	60°	45°	30°
J'	$4-5.95J'$	$1.939J'^2$	③ / ②	88.68④	18.63④	8.465④	3.252④	1.531④	.4255④	.1206④
.05	3.7025	.0048	.00130	.1152	.0244	.0111	.0042	.0020	.00056	.00016

.30	2.215	.1745	.07879	6.987	1.468	.6669	.2562	.1206	.0335	.0095
.40	1.620	.3102	.1915	16.983	3.568	1.621	.6228	.2931	.0815	.0231
.50	1.025	.4848	.4729	41.934	8.811	4.003	1.538	.7239	.2012	.0570
.60	0.430	.6980	1.6233	143.95	30.24	13.740	5.279	2.485	.6907	.1958
.65	0.1325	.8192	6.1829	548.30	115.19	52.340	20.107	9.464	2.631	.7457

The calculated values of the thrust ratio are compared with the experimental results from reference 1 in figure 9.1.1-14.

The thrust coefficient at angle of inclination and given advance ratio is then

$$C_T(\alpha,J') = C_T(0,J')\ \frac{C_T(\alpha,J')}{C_T(0,J')}$$

	$C_T(\alpha,J')$			
α	J'=.1	J'=.2	J'=.4	J'=.6
0	0.132	0.121	0.083	0.032
30	0.1321	0.1214	0.0849	0.0383
45	0.1323	0.1224	0.0898	0.0541
60	0.1331	0.1261	0.1073	0.1115
67.5	0.1344	0.1319	0.1347	0.2009
75	0.1384	0.1493	0.2175	0.4717
79.5	0.1462	0.1832	0.3791	0.9997
85	0.1987	0.4171	1.4926	4.6384

The calculated values of the thrust coefficients are compared with the experimental results from reference 1 in figure 9.1.1-15. The results may be converted to thrust in pounds by

$$-T(\alpha,J') = \frac{8}{\pi(J')^2} C_T(\alpha,J') \quad q_\infty \; S_p$$

9.1.2 PROPELLER PITCHING-MOMENT VARIATION WITH POWER AND ANGLE OF ATTACK

At the present there are no theoretical or semi-empirical methods available in the literature for the prediction of propeller pitching moments at high angles of attack. The method presented herein is empirical and requires experimental data at two moderate angles of attack.

Experimental data indicate that there is an appreciable direct pitching moment on the propeller during operation at angle of attack. This pitching moment may be regarded as being due to the fact that the center of thrust is some distance away from the center of rotation. Figures 9.1.2-3 and 9.1.2-4 show the direct propeller pitching moment expressed as an effective thrust-axis shift for the propeller and the propeller-wing combination of reference 1 and for propeller 1 of reference 2, respectively. These data indicate an increase in propeller pitching moment with increasing angle of attack and a more pronounced shift of the effective thrust axis at the lower thrust coefficients. The data of figure 9.1.2-3 further show that the propeller pitching moment was approximately doubled when the propeller was operated in the presence of the wing because of the upwash induced by the wing.

The Datcom method which follows is based on observations of the large body of test data presented in reference 2.

DATCOM METHOD

This method is suggested in reference 2 for estimating propeller pitching moment at high thrust-axis angles of attack when experimental data are available at two angles of attack, such as zero and 15 degrees.

The experimental data of reference 2 show that the propeller pitching moment for given values of blade angle and advance ratio have nearly a constant slope over wide angle-of-attack ranges at low advance ratio and that the width of these ranges diminishes with increasing advance ratio.

It is not possible to define the limits of the regions of linearity of propeller pitching moments from the experimental data as was done for the propeller thrust in Section 9.1.1. However, in view of the fact that the angle-of-attack ranges of pitching-moment linearity are essentially those over which the thrust is constant, it is assumed that, to a first approximation, the boundary, defined in figure 9.1.1-13, also applies to pitching moments. As noted in Section 9.1.1, this boundary varies with blade angle. It is defined for a blade angle typical of maximum propeller efficiency in very low-speed flight.

As a simple rule of thumb, the propeller pitching moment at high angles of attack may be obtained with accuracy acceptable for preliminary design analysis by a linear extrapolation of experimental data at moderate angles of attack, provided the modified advance ratio falls below the boundary of figure 9.1.1-13 .

9.1.3 PROPELLER NORMAL-FORCE VARIATION WITH POWER AND ANGLE OF ATTACK

Two methods are presented in this Section for estimating the propeller normal force at high angles of attack .

The first method, developed by DeYoung in reference 1, provides the normal-force coefficient at high angles of attack relative to the linear relation $\left(\frac{dC_N}{d\alpha}\right)_{\alpha=0}$ This ratio is equal to the tangent of the angle of attack, provided equal advance ratios, as determined from the velocity normal to the propeller disk, exist. In theory, the normal force is considered to be proportional to the torque difference due to angle of incidence between the down-going blade and the up-going blade.

The essential part of Datcom method 1 is the estimation of $\left(\frac{dC_N}{d\alpha}\right)_{\alpha=0}$. This involves determining the normal-force derivative with respect to the local angle of attack, the local angle-of-attack gradient, and a correction for phase-angle shift.

DeYoung, in reference 1, has obtained a simple relationship for the normal-force derivative with respect to local angle of attack in the manner described in Section 9.1. A general expression for this derivative as a function of propeller geometry and operating parameters is obtained from the analysis of Ribner in references 2 and 3 and the assumption of a blade section lift-curve slope of $c_{l_\alpha} = 0.95(2\pi)$ per radian. The constants of the resulting expression are evaluated by statistical means from the computed data of the given blade shapes of reference 4.

The normal-force derivative with respect to wing angle of attack is given as the product of the normal-force derivative with respect to the local propeller angle of attack and the local angle-of-attack gradient $\frac{d\alpha_{in}}{d\alpha}$, obtained in reference 1 by an analysis of the upwash due to the wing, fuselage, and other propellers.

Propellers operating at high angles of attack experience appreciable angle-of-attack variation on the blades. Lift increases and decreases in a harmonic fashion. As the angle of attack is increased, circulation increases, and a starting vortex is shed which induces a downwash and changes the buildup of circulation. This unsteady motion causes the lift cycle to be out of phase with the angle-of-attack cycle; consequently, the propeller forces and moments have components in both the lateral and vertical directions. The normal force at incidence is then the product of the normal force computed for zero phase angle and the cosine of the phase angle. In Datcom method 1 the effect of this phase-angle shift is applied to the computed linear relation $\left(\frac{dC_N}{d\alpha}\right)_{\alpha=0}$.

In the theory of reference 1 the propeller phase angle is approximated by an analogous wing unsteady solution, assuming that the propeller forces and blade angle of attack are analogous to those of a wing that is harmonically pitching about its quarter-chord line.

A second method is given which, in the absence of complete data on a particular propeller, can be used to approximate the normal force at large angles of attack from experimental data at small angles of attack. This approach is formulated in reference 5, wherein it is demonstrated that certain VTOL transition programs can lie within the region of linear slope of the propeller forces and moments.

DATCOM METHODS

Method 1

The variation of propeller normal force with angle of attack is given relative to $\left(\frac{dC_N}{d\alpha}\right)_{\alpha=0}$, provided equal advance ratios, as determined from the velocity normal to the propeller disk, exist. This ratio is given in reference 1 as

$$\frac{C_N\,(\alpha, J')}{C_{N_\alpha}\,(0, J')} = \tan\alpha \qquad 9.1.3\text{-a}$$

The positive normal-force and angle-of-attack senses are shown in figure 9.1-4, and the required parameters are defined in the general notation list of Section 9.1.

This method is essentially one of determining the denominator values in the form of C'_{N_α} where

$$C'_{N_\alpha} = C'_{N_{\alpha_{in}}}\,\frac{d\alpha_{in}}{d\alpha} \text{ per rad} \qquad 9.1.3\text{-b}$$

In computing these values the J or thrust in the relation for $C'_{N_{\alpha_{in}}}$ must be taken at J' and velocity at $V_\infty \cos\alpha$.

The derivatives C'_{N_α} and C_{N_α} are related by

$$C_{N_\alpha}\,(0, J') = \frac{\pi}{8}\,(J')^2\, C'_{N_\alpha}\,(0, J') \text{ per rad} \qquad 9.1.3\text{-c}$$

The procedure to be followed in evaluating the normal force is outlined in the following steps.

Step 1. Determine at zero phase angle the propeller normal-force derivative with respect to the local angle of attack at the propeller disk by

$$C'_{N_{\alpha_{in}}} = \frac{4.25\,\sigma_e}{1 + 2\,\sigma_e}\,\sin(\beta + 8)\left(1 + \frac{3T_c}{8\sqrt{1 + (2/3)T_c}}\right) \text{ per rad} \qquad 9.1.3\text{-d}$$

for single-rotation propellers, and by

$$C'_{N_{\alpha_{in}}} = \frac{3.86\,\sigma_e}{1 + \sigma_e}\,\sin(\beta + 14)\left(1 + \frac{3T_c}{8\sqrt{1 + (2/3)T_c}}\right) \text{ per rad} \qquad 9.1.3\text{-d}'$$

for counter-rotating propellers;

where σ_e is obtained as outlined in Step 1 of Datcom method 1 of Section 9.1.1 and the thrust values are taken at J', with velocity equal to $V_\infty \cos \alpha$. The thrust values will normally be known.

Step 2. Determine the local angle-of-attack gradient $\frac{d\alpha_{in}}{d\alpha}$ by

$$\frac{d\alpha_{in}}{d\alpha} = \frac{1 + \frac{2A}{9(A+10)}\left(\frac{1}{\frac{x_{L\,.75}}{c_r} + \frac{1}{10}} + \frac{1}{\frac{x_{R\,.75}}{c_r} + \frac{1}{10}}\right) + \frac{1}{2}\left[\left(\frac{R_{fus}}{y_{L\,.75}}\right)^2 + \left(\frac{R_{fus}}{y_{R\,.75}}\right)^2\right]}{1 - \frac{1}{4}\sum\limits_{\substack{\text{other}\\\text{props}}}\left[\left(\frac{R}{\Delta y_{L\,.75}}\right)^2 + \left(\frac{R}{\Delta y_{R\,.75}}\right)^2\right]\frac{d\epsilon_{z\,slip}}{d\alpha_{in}}} \qquad 9.1.3\text{-e}$$

where the first two terms in the numerator are the average upwash at the propeller .75R station due to the wing, and the third term in the numerator is the average upwash at the propeller .75R station due to the fuselage.

The summation term in the denominator is the average downwash in the propeller slipstream at the propeller .75R station. For propellers operating near each other this downwash must be considered in predicting the local angle-of-attack gradient. This downwash may be neglected if a fuselage separates the propellers or if adjacent propellers are sufficiently far apart so that $\Delta y > 2R$. The slipstream gradient is given by

$$\frac{d\epsilon_{z_{slip}}}{d\alpha_{in}} = \frac{T_c}{4 + \frac{8}{7}T_c} + \frac{\left(C'_{N_{\alpha_{in}}}\right)_{T_c=0}\sqrt{1 + 1.3\,T_c}}{4 + 2T_c} \qquad 9.1.3\text{-f}$$

Step 3. Determine the propeller normal-force derivative with respect to wing angle of attack at zero phase angle using the terms obtained in Steps 1 and 2 and equation 9.1.3-b

$$C'_{N_\alpha} = C'_{N_{\alpha_{in}}}\frac{d\alpha_{in}}{d\alpha} \text{ per rad}$$

Step 4. Correct the C'_{N_α} value obtained for zero phase angle (Step 3) for phase-angle shift by

$$C'_{N_\alpha}(\delta) = C'_{N_\alpha}\cos\delta_f \text{ per rad} \qquad 9.1.3\text{-g}$$

The phase angle is determined by

$$\delta_f = 0.825 \tan^{-1} \frac{15\, \sigma_e}{B\sqrt{2\, J_{\alpha_P}\, J' - (J')^2}} \qquad 9.1.3\text{-h}$$

where

$$J_{\alpha_P} = J_{\alpha_T} + \frac{16}{\sin\,(\beta + 5)\, \cos^4\,(\beta + 5)} \left(\frac{\sigma_e}{B}\right)^2 \qquad 9.1.3\text{-i}$$

and J_{α_T} is obtained as a function of β from Figure 9.1.1-7.

Step 5. Convert the $C_{N'_\alpha}$ results of Step 4 to C_{N_α} using equation 9.1.3-c.

$$C_{N_\alpha}\,(0,J') = \frac{\pi}{8}\,(J')^2\, C_{N'_\alpha}\,(0,J') \quad \text{per rad}$$

Step 6. Determine the normal force at selected wing angles of attack and modified advance ratios using

$$C_N\,(\alpha,J') = C_{N_\alpha}\,(0,J')\,\tan\alpha$$

A comparison of normal-force derivative at zero thrust, computed using equations 9.1.3-d and 9.1.3-d', with the theory of reference 4 is presented in Table 9.1.3-A. The percentage difference shown has been taken with respect to the values of reference 4. The comparison includes data with two blade shapes and wide variations of solidity, blade pitch angles, and number of blades. The percentage difference is considered to be within the accuracy of detailed propeller theory.

The normal-force ratio given by equation 9.1.3-a is compared with experimental data from reference 5 in figure 9.1.3-14.

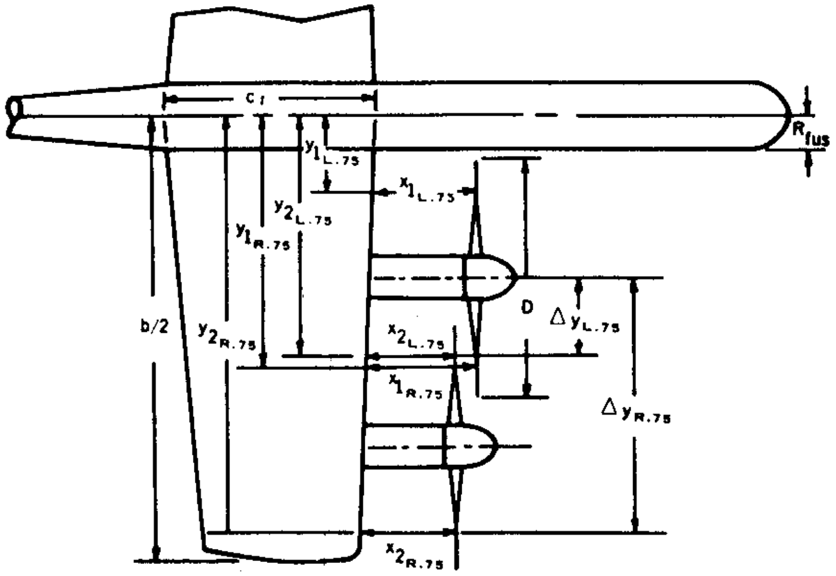
Method 2

This method is suggested in reference 5 for estimating the propeller normal force at high angles of attack when experimental data are available at two angles of attack, such as zero and 15 degrees. This is an empirical method based on observations of a large body of test data in reference 5. The method is analogous to the method of Section 9.1.2 for estimating propeller pitching moments and provides acceptable accuracy for preliminary-design analysis. The method merely states that the propeller normal force at high angles of attack may be obtained by linear extrapolation of experimental data, provided the modified advance ratio falls below the boundary of figure 9.1.1-13.

Sample Problem

Method 1

Given: The hypothetical four-propeller, tilt-wing airplane of reference 6 with linear dimensions six times those of the model. The propellers are those designated as propeller 1 of reference 5. The following example is computed for four values of the modified advance ratio over an angle-of-attack range from 0 to 80 degrees.



Propeller Characteristics

The propellers are the same as those of the sample problem of Section 9.1.1.

$B = 3$ $\quad$ $D = 12$ ft $\quad$ $\beta = 12^{\circ}$ $\quad$ $\sigma_e = 0.117$ $\quad$ $J_{OT} = 0.6725$

J'	0.1	0.2	0.4	0.6
T_c (0, J')	33.61	7.703	1.321	0.2267

These T_c (0,J') values have been obtained from the C_T (0,J') values given in the sample problem of Section 9.1.1 by

$$T_c\ (0,J') = \frac{8}{\pi\ (J')^2}\ C_T\ (0,J')$$

Airplane Characteristics

$c_r = 10.0$ ft $A = 4.89$ $R_{fus} = 1.25$ ft

Propeller 1 (Inboard)		Propeller 2 (Outboard)	
$x_{L\ .75} = 5.25$ ft	$y_{L\ .75} = 3.25$ ft	$x_{L\ .75} = 4.50$ ft	$y_{L\ .75} = 11.75$ ft
$x_{R\ .75} = 5.60$ ft	$y_{R\ .75} = 12.25$ ft	$x_{R\ .75} = 4.80$ ft	$y_{R\ .75} = 20.75$ ft

$\Delta y_{L\ .75} = 4.0$ ft

$\Delta y_{R\ .75} = 13.0$ ft

Compute:

Step 1. Determine the propeller normal-force derivatives at zero phase angle with respect to the local angle of attack at the propeller disk $C_{N'_{\alpha_{in}}}$

$$C_{N'_{\alpha_{in}}} = \frac{4.25\ \sigma_e}{1 + 2\ \sigma_e} \sin\ (\beta + 8) \left(1 + \frac{3T_c}{8\sqrt{1 + (2/3)T_c}}\right) \text{per rad}$$

(equation 9.1.3-d)

$$= \frac{(4.25)(0.117)}{1 + 2\ (0.117)} \sin\ (12 + 8) \left(1 + \frac{3T_c}{8\ \sqrt{1 + (2/3)T_c}}\right)$$

$$= 0.138 + \frac{0.0517T_c}{\sqrt{1 + (2/3)T_c}}$$

TABLE I

① J'	② T_c	③ $0.0517T_c$ 0.0517 ②	④ $\sqrt{1 + (2/3)\ T_c}$ $\sqrt{1 + (2/3)}$ ②	⑤ $C_{N'_{\alpha_{in}}} - 0.138$ ③/④	⑥ $C_{N'_{\alpha_{in}}}$ (1/rad) 0.138 + ⑤
0.1	33.61	1.74	4.84	0.3600	0.498
0.2	7.703	0.398	2.48	0.1600	0.298
0.4	1.321	0.0683	1.371	0.0498	0.1878
0.6	0.2267	0.0117	1.072	0.0109	0.1489

Step 2. Determine the local angle-of-attack gradient $d\alpha_{in}/d\alpha$.

For this configuration $\Delta y < 2R$ and the propeller downwash effect on the local angle-of-attack gradient must be considered.

$$\frac{d\alpha_{in}}{d\alpha} = \frac{1 + \frac{2A}{9(A+10)}\left(\frac{1}{\frac{x_{L\,.75}}{c_r} + \frac{1}{10}} + \frac{1}{\frac{x_{R\,.75}}{c_r} + \frac{1}{10}}\right) + \frac{1}{2}\left[\left(\frac{R_{fus}}{y_{L\,.75}}\right)^2 + \left(\frac{R_{fus}}{y_{R\,.75}}\right)^2\right]}{1 - \frac{1}{4}\sum_{\text{prop 1}}^{\text{prop 2}}\left[\left(\frac{R}{\Delta y_{L\,.75}}\right)^2 + \left(\frac{R}{\Delta y_{R\,.75}}\right)^2\right]\frac{d\epsilon_{z\ slip}}{d\alpha_{in}}}$$

(equation 9.1.3-e)

Propeller 1 (Inboard)

$$\left(\frac{d\alpha_{in}}{d\alpha}\right)_1 = \frac{1 + \frac{2(4.89)}{9(4.89 + 10)}\left(\frac{1}{\frac{5.25}{10} + \frac{1}{10}} + \frac{1}{\frac{5.60}{10} + \frac{1}{10}}\right) + \frac{1}{2}\left[\left(\frac{1.25}{3.25}\right)^2 + \left(\frac{1.25}{12.25}\right)^2\right]}{1 - \frac{1}{4}\left[\left(\frac{6.0}{4.0}\right)^2 + \left(\frac{6.0}{13.0}\right)^2\right]\frac{d\epsilon_{z_{slip}}}{d\alpha_{in}}}$$

$$= \frac{1 + 0.073\left(\frac{1}{0.625} + \frac{1}{0.660}\right) + \frac{1}{2}(0.148 + 0.0104)}{1 - 0.25\,(2.25 + 0.213)\,\frac{d\epsilon_{z_{slip}}}{d\alpha_{in}}}$$

$$= \frac{1 + 0.073\,(3.115) + 0.0792}{1 - 0.25\,(2.463)\,\frac{d\epsilon_{z_{slip}}}{d\alpha_{in}}}$$

$$= \frac{1.3067}{1 - (0.616)\,\frac{d\epsilon_{z_{slip}}}{d\alpha_{in}}}$$

Propeller 2 (Outboard)

$$\left(\frac{d\alpha_{in}}{d\alpha}\right)_2 = \frac{1 + 0.073\left(\frac{1}{\frac{4.50}{10} + \frac{1}{10}} + \frac{1}{\frac{4.80}{10} + \frac{1}{10}}\right) + \frac{1}{2}\left[\left(\frac{1.25}{11.75}\right)^2 + \left(\frac{1.25}{20.75}\right)^2\right]}{1 - (0.616)\,\frac{d\epsilon_{z_{slip}}}{d\alpha_{in}}}$$

$$= \frac{1 + 0.073\left(\frac{1}{0.550} + \frac{1}{0.580}\right) + \frac{1}{2}\,(0.0113 + 0.0036)}{1 - (0.616)\,\frac{d\epsilon_{z_{slip}}}{d\alpha_{in}}}$$

$$= \frac{1 + 0.073\ (3.542) + 0.00745}{1 - (0.616)\,\frac{d\epsilon_{z_{slip}}}{d\alpha_{in}}}$$

$$= \frac{1.266}{1 - (0.616)\,\frac{d\epsilon_{z_{slip}}}{d\alpha_{in}}}$$

$$\left(C_{N_{\alpha'}{}_{in}}\right)_{T_c=0} = 0.138 \quad \text{(step 1 with } T_c=0\text{)}$$

$$\frac{d\epsilon_{z_{slip}}}{d\alpha_{in}} = \frac{T_c}{4 + \frac{8}{7}T_c} + \frac{\left(C_{N'_{\alpha_{in}}}\right)_{T_c=0}\sqrt{1 + 1.3\ T_c}}{4 + 2\ T_c} \quad \text{(equation 9.1.3-f)}$$

$$= \frac{T_c}{4 + \frac{8}{7}T_c} + \frac{0.138\sqrt{1 + 1.3\ T_c}}{4 + 2\ T_c}$$

TABLE II

①	②	③	④	⑤	⑥	⑦	⑧
J'	T_c	$4 + \frac{8}{7}T_c$	$\frac{T_c}{③}$	$\sqrt{1 + 1.3\ T_c}$	$4 + 2\ T_c$	$\frac{0.138\ ⑤}{⑥}$	$d\epsilon_{z_{slip}}/d\alpha_{in}$ ④ + ⑦
0.1	33.61	42.41	0.7925	6.69	71.22	0.0130	0.8055
0.2	7.703	12.80	0.6018	3.32	19.41	0.0236	0.6254

0.2	0.6254	0.6148	2.125	2.059
0.4	0.2740	0.8312	1.572	1.523
0.6	0.0885	0.9455	1.382	1.339

Step 3. Determine the propeller normal-force derivatives at zero phase angle with respect to wing angle of attack $C_{N'_\alpha}$

$$C_{N'_\alpha} = C_{N'_{\alpha_{in}}} \frac{d\alpha_{in}}{d\alpha} \quad \text{per rad} \qquad \text{(equation 9.1.3-b)}$$

TABLE IV

① J'	② $C_{N'_{\alpha_{in}}}$ (1/rad) Col. ⑥, Table I	③ $(C_{N'_\alpha})_1$ (1/rad) Col. ④, Table III x ②	④ $(C_{N'_\alpha})_2$ (1/rad) Col. ⑤, Table III x ②
0.1	0.498	1.292	1.251
0.2	0.298	0.633	0.614
0.4	0.1878	0.295	0.286
0.6	0.1489	0.206	0.199

Step 4. Correct the $C_{N'_\alpha}$ values obtained in step 3 for phase-angle shift.

$$J_{o_P} = J_{o_T} + \frac{16}{\sin(\beta + 5)\cos^4(\beta + 5)}\left(\frac{\sigma_e}{B}\right)^2 \qquad \text{(equation 9.1.3-i)}$$

$$= 0.6725 + \frac{16}{\sin(17)\cos^4(17)}\left(\frac{0.117}{3}\right)^2$$

$$= 0.6725 + \frac{16}{(0.2924)(0.9563)^4}(0.00152)$$

$$= 0.6725 + 0.0995$$

$$= 0.772$$

$$\delta_f = 0.825 \tan^{-1} \frac{15 \sigma_e}{B\sqrt{2 J_{o_p} J' - (J')^2}} \qquad \text{(equation 9.1.3-h)}$$

$$= 0.825 \tan^{-1} \frac{15(0.117)}{3\sqrt{2(0.772)(J') - (J')^2}}$$

$$= 0.825 \tan^{-1} \frac{0.585}{\sqrt{1.544 J' - (J')^2}}$$

TABLE V

①	②	③	④	⑤	⑥	⑦	⑧
J'	$(J')^2$ $①^2$	1.544 J' 1.544 ①	$1.544 J' - (J')^2$ ③ - ②	$\sqrt{④}$	$\frac{0.585}{⑤}$	$\tan^{-1}$ ⑥ (deg)	δ_f (deg) 0.825 ⑦

0.6	0.36	0.1414	0.0249	0.0240

Solution:

The variation of propeller normal-force coefficient with angle of attack at the chosen values of J' is tabulated below using

$$C_N\ (\alpha,\ J') = C_{N_\alpha}\ (0,\ J')\ \tan\alpha \quad \text{(equation 9.1.3-a)}$$

for both the inboard and outboard propellers.

$C_N\ (\alpha,\ J')$

		Propeller 1 (Inboard)				Propeller 2 (Outboard)			
α	$\tan\alpha$	J' = 0.1	0.2	0.4	0.6	J' = 0.1	0.2	0.4	0.6

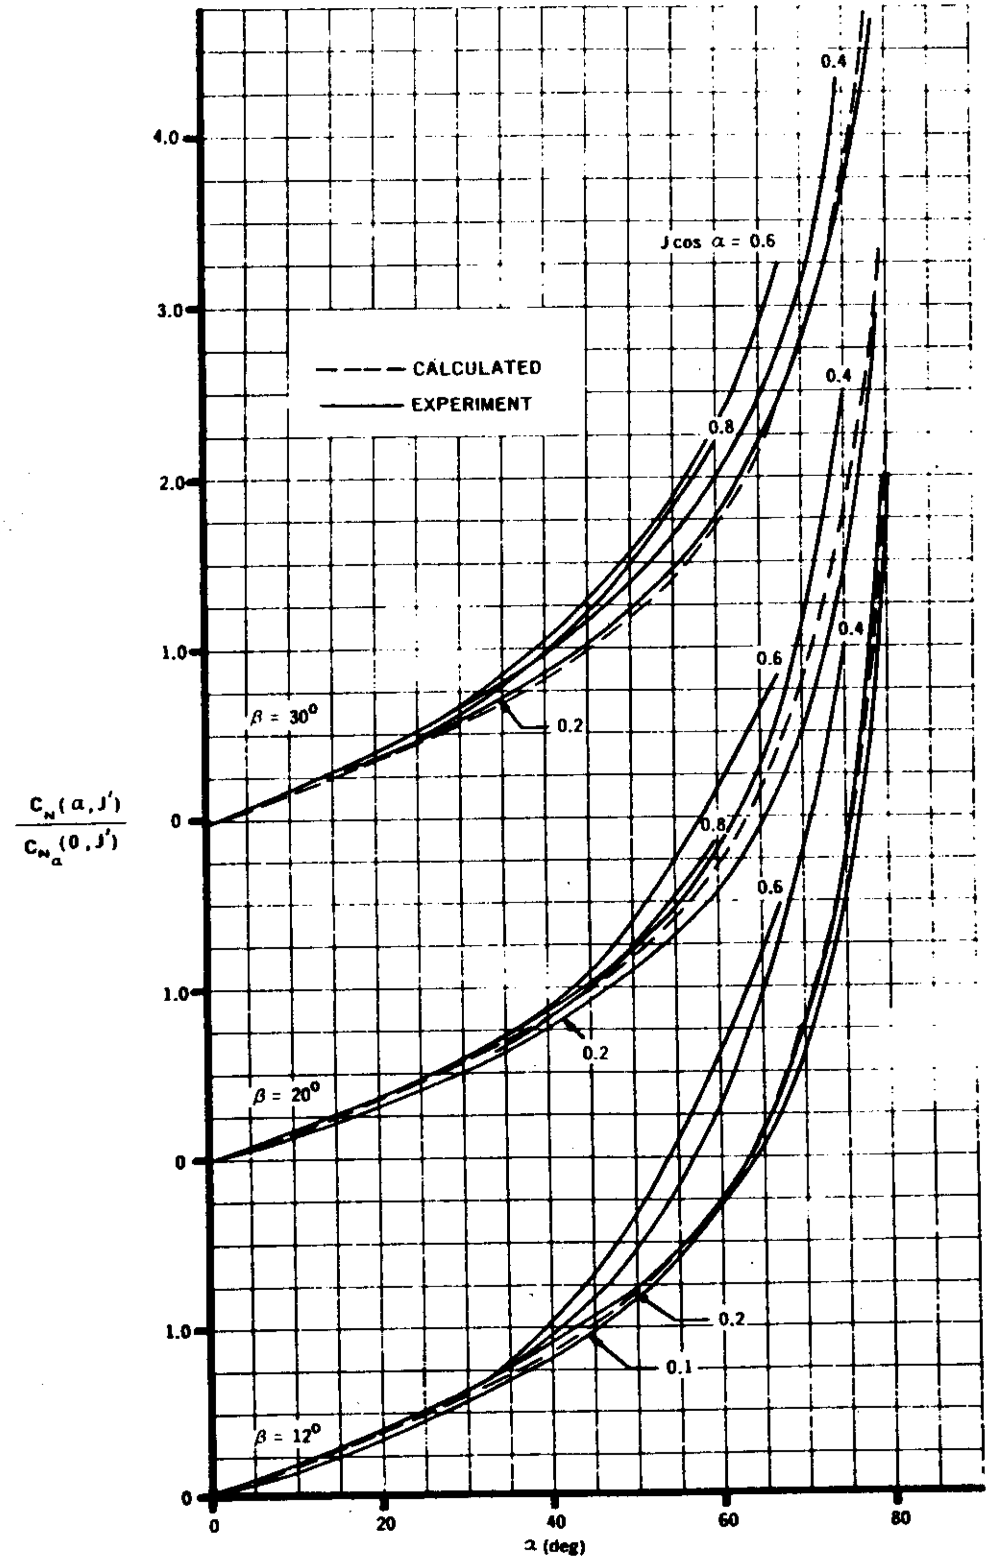

FIGURE 9.1.3-14 COMPARISON OF CALCULATED AND EXPERIMENTAL NORMAL-FORCE RATIO WITH PROPELLER THRUST-AXIS ANGLE OF ATTACK FOR PROPELLER 1 OF REFERENCE 5

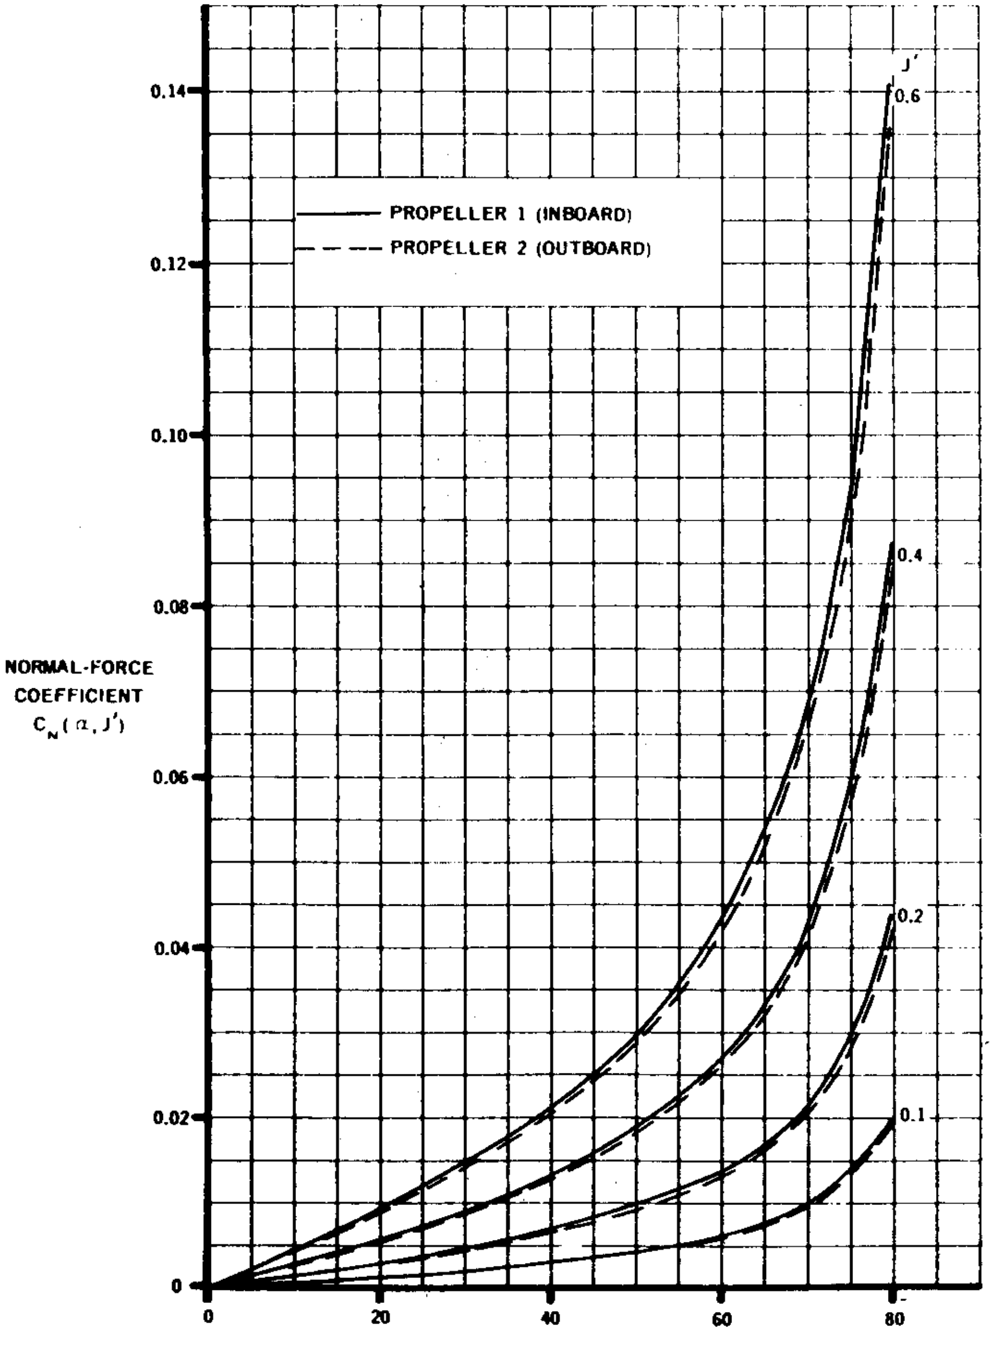

FIGURE 9.1.3-15 VARIATION OF PROPELLER NORMAL-FORCE COEFFICIENT WITH ANGLE OF ATTACK AND MODIFIED ADVANCE RATIO FOR INBOARD AND OUTBOARD PROPELLERS OF A HYPOTHETICAL 4-PROPELLER TILT-WING AIRPLANE. SAMPLE PROBLEM, METHOD 1

9.2 PROPELLER-WING CHARACTERISTICS

The methods of this section are for prediction of the power-on lift and drag forces of propeller-wing combinations of V/STOL aircraft and deal primarily with the low-speed, high-power flight regime where wing stalling tendencies at high angles of attack are delayed by power effects.

The usual approach to attaining V/STOL capabilities is to use power plant thrust to obtain lift at low speeds. Propeller-driven V/STOL configurations, other than those employing ducted propellers, consist basically of three types:

1. Deflected slipstream
2. Tilt wing
3. Combination tilt wing – deflected slipstream

These configurations differ in detail, but each employs interacting wing and thrust systems. In treating such configurations in the low-speed, high-power flight regime we must abandon the familiar distinction between lifting and thrusting systems and combine them.

Several factors dealing with propeller slipstream flow over a wing are of special significance. The local angles of attack of a propeller-wing combination in transition are determined by vector addition of the free-stream and propeller slipstream velocities. The propeller slipstream is a strong factor in reducing the local angles of attack and thereby minimizing the tendency of wing stall. Stalls may occur even in the presence of the slipstream if the slipstream velocity is low.

Since the velocity of the slipstream relative to that of the free stream is increased by increased disk loading, stalling tendencies are decreased by increasing the propeller disk loading. Wing stall can be avoided entirely by immersing the entire wing in the propeller slipstream, provided sufficient thrust is generated by the propellers.

Experimental studies have been conducted to determine the spanwise distribution of the lift increase due to the slipstream at different angles of attack with various free-stream-to-slipstream velocity ratios. The results of these tests, reported in reference 7, indicate that the lift increment due to the passage of a slipstream over a wing consists of two parts:

1. A direct lift gain which can be accurately predicted by potential flow theory.
2. A lift increment due to a "destalling" or boundary-layer-control effect. This "destalling" effect extends to portions of the wing outside the propeller slipstream and improves the wing stalling behavior.

The results also indicate that the limits of the direct slipstream influence are sharply defined and do not vary with wing angle of attack and slipstream strength.

Both references 7 and 61 indicate that the rotation of the propeller slipstream causes an upwash over the wing behind the upward moving blade. This area will generally be the first to stall on a wing that is fully immersed in propeller slipstreams. The effect of propeller rotation on maximum lift was investigated in reference 20, wherein it is concluded that slightly larger values of maximum lift can be generated when propellers rotate with the inboard tips moving up. This lift increase is attributed to a reduction in tip losses resulting from the propeller rotating in such a manner as to oppose the wing-tip vortex and to the fact that the upwash behind the upward moving blade is not entirely cancelled by the downflow at the wing tip.

Propeller-wing combinations in the transition region do not lend themselves to theoretical analysis. The Datcom methods for the prediction of lift and drag forces at forward speed with power on comprise semiempirical expressions from reference 52. These methods employ momentum theory as a starting point. They are based on power-off data and a correlation of slipstream-deflection data at zero forward speed. The correlation of slipstream-deflection data is based on numerous static investigations of a limited number of wing-flap systems. Effects of various parameters on the slipstream-deflection characteristics are summarized in reference 52.

The methods are applicable only in the unstalled flight regime. Comparison of experimental results with calculations made using the Datcom methods indicate that, in general, the estimation procedures give reasonably good results for steady level flight and for climbing flight. Through judicious use of the Datcom methods the lift and drag forces can be estimated for deflected-slipstream, tilt-wing, and combination tilt-wing – deflected-slipstream configurations. At the present time there are no methods available for the prediction of the pitching moment of a propeller-wing configuration in the transition flight regime.

Numerous static and forward speed investigations have been conducted on propeller-driven V/STOL configurations. However, the number of specific designs tested has been so limited that the substantiation of any semiempirical method developed for the prediction of forces and moments has not been possible. Furthermore, excessive wind-tunnel wall effects during simulated low-speed, high-power flight conditions invalidate many investigations.

A comprehensive tabulation of pertinent propeller-wing experimental data is presented as table 9.2-A. This table provides a brief outline of the test data contained in each report and indicates the basic parametric changes made. Additional reports, dealing with complete configurations, can be found in the VTOL-STOL summary table of Section 9.

A general notation list is included in this section for all propeller-wing combination sections. Coefficients are based on the dynamic pressure in the propeller slipstream unless otherwise noted. The conversion from coefficients based on slipstream dynamic pressure to coefficients based on free-stream dynamic pressure is presented at the end of the notation list.

The positive direction of forces and angles is shown in figure 9.2-9.

NOTATION

c	average wing chord, ft
ΔC_D	zero-lift drag increment due to flap deflection based on free-stream velocity
C_{D_f}	power-off zero-lift drag coefficient based on free-stream velocity
C_{D_o}	power-off drag coefficient based on free-stream velocity, $\frac{\text{Drag}}{q_\infty S}$
c_f	average flap chord, ft
C_{F_x}	negative-drag coefficient based on free-stream velocity, $\frac{F_x}{q_\infty S}$
C_{F_x}''	negative-drag coefficient based on slipstream velocity, $\frac{F_x}{q'' S}$
C_{L_o}	power-off lift coefficient based on free-stream velocity, $\frac{L}{q_\infty S}$
C_L''	lift coefficient based on slipstream velocity, $\frac{L}{q'' S}$
D	propeller diameter, ft
e	span efficiency factor
F	resultant force, lb
F_x	horizontal force, lb
$\frac{F}{T}$	thrust-recovery factor
i_W	wing incidence measured between thrust axis and wing chord plane, deg
J	advance ratio, $\frac{V_\infty}{nD}$
K	number of propellers

L	lift, lb
q_∞	free-stream dynamic pressure, lb/sq ft
q''	slipstream dynamic pressure, $q_\infty + \frac{T}{S_p}$, lb/sq ft
S	wing area, sq ft
S_p	propeller disk area, $\frac{\pi}{4} D^2$, sq ft
T	thrust per propeller or total thrust when used in thrust-recovery factor, lb
T_c	propeller thrust coefficient based on free-stream velocity and wing area, $\frac{KT}{q_\infty S}$
T_c''	propeller thrust coefficient based on slipstream velocity and propeller disk area, $\frac{T}{q'' S_p}$
α	angle of attack measured between free stream and thrust axis, deg
δ	flap deflection, deg
δ_e	equivalent flap deflection due to wing camber and incidence, deg
θ	slipstream turning angle measured from thrust axis, deg
θ_f	slipstream turning angle adjusted to the condition of zero camber and zero incidence, deg
$\Delta\theta$	increment of slipstream turning angle due to wing camber and incidence, deg

Conversion between systems:

(Unprimed coefficients are based on free-stream dynamic pressure.)

$$C_D = \frac{-C_{F_x}''}{1 - T_c''} \qquad C_{F_x}'' = \frac{-C_D}{1 + T_c \frac{S}{KS_p}} \qquad T_c = \frac{T_c''}{1 - T_c''} \frac{KS_p}{S}$$

$$C_L = \frac{C_L''}{1 - T_c''} \qquad C_L'' = \frac{C_L}{1 + T_c \frac{S}{KS_p}} \qquad T_c'' = \frac{T_c}{T_c + \frac{KS_p}{S}}$$

$$q_\infty = q'' (1 - T_c'')$$

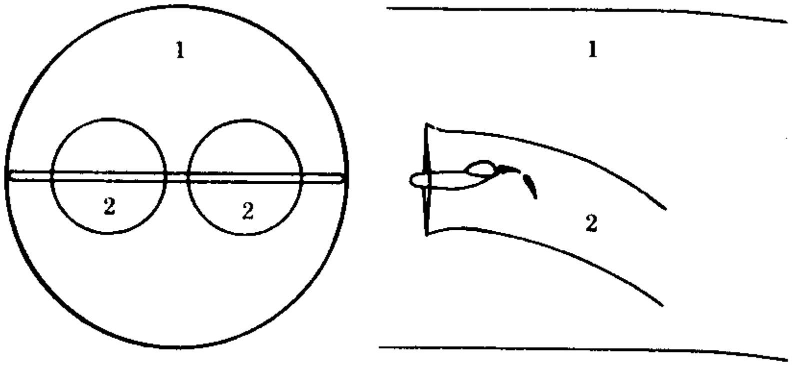
9.2.1 PROPELLER-WING-FLAP LIFT VARIATION WITH POWER AND ANGLE OF ATTACK

The methods for calculating power-on lift and drag forces of tilt-wing and deflected-slipstream configurations are those developed by Kuhn in reference 1. The methods treat the flow system of a propeller-wing-flap configuration as two separate mass flows, each deflected through a different angle by the wing. The two mass flows are (1) the mass flow deflected downward by the wing through small to moderate angles and (2) the mass flow in slipstreams created by the action of the propellers and deflected downward through large angles by either tilting the thrust axis or deflecting the flaps. These flow systems are illustrated in sketch (a).



SKETCH (a)

The forces generated in deflection of these mass flows are the familiar lift, induced drag, and profile drag of a wing in a free stream; the propeller thrust which accelerates the propeller slipstream; and a force which accounts for deflection of the propeller slipstream by the wing. Kuhn has analyzed the forces arising from the deflection of each mass flow separately and combined them to arrive at a semiempirical method based on simple momentum theory to estimate the lift and drag forces of propeller-wing-flap configurations. The method uses static slipstream deflection data and power-off wing-flap data as the basis for the calculations.

Kuhn develops expressions for both the lift and drag forces in cruising and high-speed flight by neglecting the forces due to the propeller slipstream and treating the deflection of the mass flow affected by the wing within the assumption of simple momentum thoery. Using this assumption at very low cruising speeds requires that the stream tube be deflected through large angles with a minimum loss in order to produce enough lift to support the airplane. Although the validity of extrapolation of simple momentum theory to large angles appears to be a rather gross assumption, the theory gives reasonable results as long as stall can be avoided.

At zero forward speed, only the propeller slipstreams are available to produce thrust and lift. At this end of the speed range Kuhn develops expressions for the lift and drag forces from available static experimental data on the effectiveness of wing-flap systems in deflecting propeller slipstreams. These expressions are presented in terms of propeller thrust, slipstream characteristics, and the turning effectiveness parameters θ and $\frac{F}{T}$. The slipstream characteristics are obtained using simple momentum theory as applied to propellers.

At transition speeds both flow regions are considered. The resulting expressions approach the power-off wing expressions as velocity is increased and thrust reduced to zero, and approach the zero-forward-speed expressions as the speed is reduced to zero. The method thus provides a logical means of interpolating between these end points.

In treating the flow in the two systems, the fact that the propeller slipstreams occupy space within the large wing stream tube is compensated for by assuming the propeller slipstream to be fully contracted at the wing and that the contraction does not alter the diameter of the stream tube affected by the wing.

To determine the velocity increments necessary to calculate momentum changes, Kuhn assumes that the propeller slipstreams are deflected through the turning angle θ obtained at zero forward speed, that the stream tube affected by the wing is deflected through the downwash angle ϵ obtained under power-off conditions, and that both θ and ϵ remain constant with changes in speed and power.

In order to apply the Datcom methods, it is necessary to have experimental results for or to be able to estimate power-off lift and drag-force characteristics of the wing, as well as slipstream deflection characteristics of the propeller-wing-flap configuration at zero forward speed. The slipstream deflection characteristics for a given propeller-wing-flap configuration require experimental static-thrust data, which will more than likely not be available during the preliminary design phase. Therefore design charts, taken from reference 1, for the slipstream deflection characteristics are provided.

The method presented in this Section is for estimation of the lift of propeller-wing-flap configurations at combined forward speed and power-on conditions. The method is applicable only in the unstalled region of flight.

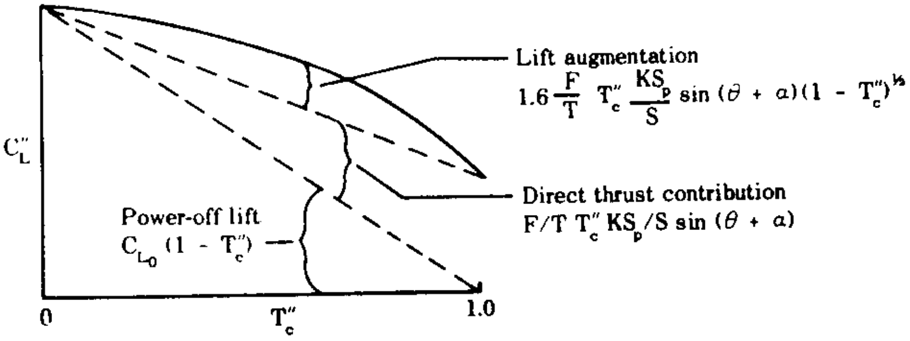
DATCOM METHOD

The lift of a propeller-wing-flap configuration at combined forward speed and power-on conditions is given in reference 1 as

$$C_L'' = C_{L_o}\left(1 - T_c''\right) + \frac{F}{T} T_c'' \frac{KS_p}{S} \sin\left(\theta + \alpha\right)\left[1 + 1.6\left(1 - T_c''\right)^{1/2}\right] \qquad 9.2.1\text{-a}$$

where all the parameters are defined in the general notation list of Section 9.2. The coefficients, except for C_{L_o}, are based on the dynamic pressure in the propeller slipstream, and the positive direction of forces and angles is shown in Figure 9.2-6.

The first term of equation 9.2.1-a represents the power-off lift contribution. The last term represents both the direct propeller thrust contribution and the lift augmentation of the wing due to the propeller slipstream. The significance of these terms is illustrated in sketch (b).



SKETCH (b)

The procedure to be followed in evaluating equation 9.2.1-a is outlined in the following steps.

Step 1. Determine the slipstream turning angle θ by

$$\theta = \theta_f + \Delta\theta \tag{9.2.1-b}$$

where

θ_f is the slipstream turning angle under conditions of zero incidence and zero camber

$\Delta\theta$ is the slipstream turning-angle increment due to wing camber and incidence between the wing-chord plane and the thrust axis

θ_f is obtained by

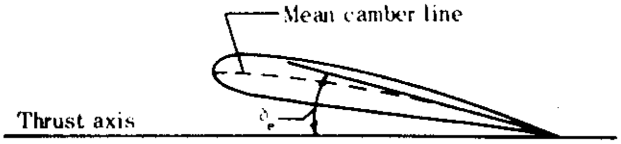
$$\theta_f = \frac{\theta}{\delta}\,\delta \tag{9.2.1-c}$$

where $\frac{\theta}{\delta}$ is obtained from figure 9.2.1-18a as a function of the ratio of the total extended flap chord to the propeller diameter $\frac{c_f}{D}$, and δ is the total flap deflection. For a multiple-flapped configuration the total flap deflection is the sum of the flap deflection of each individual flap.

$\Delta\theta$ is obtained by

$$\Delta\theta = \frac{\theta}{\delta}\,\delta_e \tag{9.2.1-d}$$

where $\frac{\theta}{\delta}$ is obtained from Figure 9.2.1-18a as a function of the ratio of the wing chord to the propeller diameter $\frac{c}{D}$, and δ_e is an equivalent flap deflection angle defined as the angle between the thrust axis and the mean camber line at the wing trailing edge (see sketch (c)).



SKETCH (c)

In using this procedure to determine the slipstream turning angle, it is necessary that the value be obtained over the linear part of the curve of variation of turning angle with flap deflection.

In order to define the region of linearity for a given flap configuration, a curve of the variation of the maximum turning angle θ_{max} with the ratio of the total flap chord to the propeller diameter $\frac{c_f}{D}$ is given as figure 9.2.1-18b. A comparison of Figures 9.2.1-18a and 9.2.1-18b indicates that the slope $\frac{\theta}{\delta}$ is dependent only on the total flap chord; whereas the maximum turning angle is dependent upon both the total flap chord and the type of flap. The slope $\frac{\theta}{\delta}$ will become nonlinear as θ_{max} for a given flap configuration is approached. For the purpose of the Datcom the range of the linear variation of θ with δ is defined as

$$\frac{\theta_f}{\theta_{max}} \leq 0.95$$

Step 2. Determine the thrust-recovery factor $\frac{F}{T}$ from figure 9.2.1-19 as a function of the turning angle θ (obtained in Step 1), the flap configuration, and the propeller arrangement.

Step 3. Determine the power-off lift coefficient C_{L_0}.

A wing which is stalled in the power-off condition would frequently be unstalled at some moderate to high propeller thrust coefficient. In order to estimate the power-on data in this region, it is necessary to use the lift values that would exist if the wing were unstalled in the power-off condition. Where possible, experimental power-off data should be used and extrapolated for this purpose. Under these conditions the power-off lift coefficient can be estimated by

$$C_{L_0} = C_{L_{\alpha_0}} 57.3 \sin (\alpha - \alpha_0) \qquad 9.2.1\text{-e}$$

where $C_{L_{\alpha_0}}$ is the extrapolated power-off lift-curve slope of the wing-flap configuration, per degree, and α_0 is the extrapolated power-off zero-lift angle of attack.

If power-off data for the given configuration are not available or if the power-off data do not exhibit any region of unstalled flow, the following procedure can be used:

(a) Determine the unflapped wing zero-lift angle of attack from Section 4.1.3.1.

(b) Determine the wing-flap incremental lift from Section 6.1.4.1.

(c) Determine the power-off lift-curve slope of the flapped wing from Section 6.1.4.2.

(d) Using the parameters determined in (a), (b), and (c) construct the power-off lift curve of the flapped wing to obtain α_o.

(e) The power-off lift coefficient of the flapped wing at angle of attack is then obtained using equation 9.2.1-e.

Step 4. The propeller thrust coefficient T_c'' will usually be specified; however, if necessary this parameter can be estimated using the method of Section 9.1.1. (Note that $T_{c_{9.2.1}} = T_{c_{9.1.1}} \frac{S_p}{S}$, and $T_c'' = \frac{T_{c_{9.1.1}}}{T_{c_{9.1.1}} + K}$.)

Step 5. The lift coefficient is then obtained from equation 9.2.1-a.

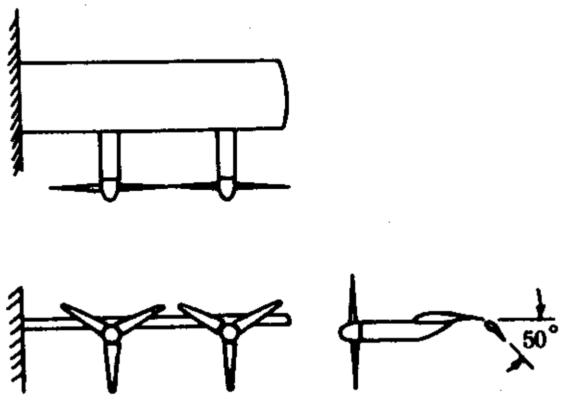
The sample problems illustrate the use of the Datcom method in estimating the lift coefficients of both deflected-slipstream and tilt-wing configurations.

Comparison of experimental data, in the unstalled flight regime, with calculations made using the Datcom method is presented for deflected-slipstream and tilt-wing configurations in Table 9.2.1-A.

Sample Problems

1. Deflected-Slipstream Configuration

Given: A propeller-wing-flap deflected-slipstream configuration of reference 2.



Wing Characteristics

$S = 10.96$ sq ft $\qquad A = 7.66 \qquad$ NACA 4415 airfoil section

$i_W = 0^\circ \qquad c = 1.2$ ft (flap retracted) $\quad c = 1.68$ ft (Fowler flap extended)

Flap Characteristics

Fowler flap $\qquad \frac{c_f}{c} = 0.286$ (flap extended) $\qquad \delta = 50^\circ$

Propeller Characteristics

$K = 4$ (2 propellers per semispan, no overlap) $\qquad D = 2.0$ ft

$S_p = 3.14$ sq ft

Additional Characteristics

$T_c'' = 0.90 \qquad \delta_e = 7.4^\circ$

Compute:

Step 1. Determine the slipstream turning angle θ.

$$\frac{c_f}{D} = \frac{c_f}{c}\frac{c}{D} = (0.286)\left(\frac{1.68}{2.0}\right)$$

$$= 0.24$$

$\frac{\theta}{\delta} = 0.50$ (figure 9.2.1-18a at $\frac{c_f}{D} = 0.24$)

$\theta_f = \frac{\theta}{\delta}\delta = (0.50)(50)$ (equation 9.2.1-c)

$$= 25^\circ$$

Assuming the wing to be a large-chord flap

$$\frac{c}{D} = \frac{1.2}{2.0} = 0.60$$

$\frac{\theta}{\delta} = 0.803$ (figure 9.2.1-18a at $\frac{c}{D} = 0.6$)

$\Delta\theta = \frac{\theta}{\delta}\delta_e = (0.803)(7.4)$ (equation 9.2.1-d)

$$= 5.94$$

$\theta = \theta_f + \Delta\theta = 25 + 5.94$ (equation 9.2.1-b)

$$= 30.94^\circ$$

Determine if the $\frac{\theta}{\delta}$ value for this wing-flap configuration is in the linear range.

$\theta_{max} = 26.5^\circ$ (figure 9.2.1-18b at $\frac{c_f}{D} = 0.24$)

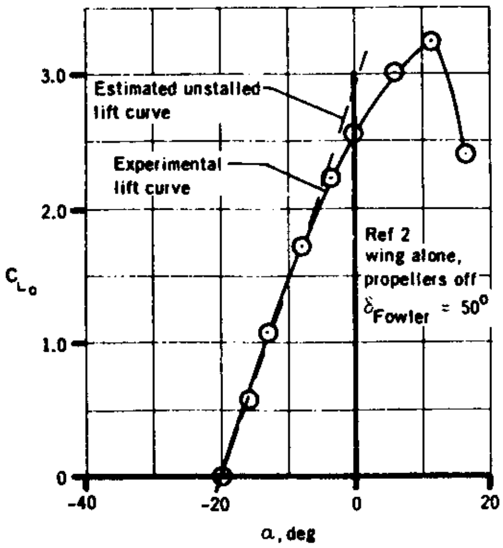
$\frac{\theta_f}{\theta_{max}} = \frac{25}{26.5} = 0.943$ which is within the range of the linear variation of θ with δ as defined by the Datcom.

Step 2. Determine the thrust-recovery $\frac{F}{T}$.

$\frac{F}{T} = 0.96$ (figure 9.2.1-19)

Step 3. Determine the power-off lift coefficient C_{L_o}.

The experimental power-off lift curve is extrapolated to obtain



$\alpha_o = -20^\circ$

$C_{L_{\alpha_o}} = 0.145$ per deg

The lift curve that would exist if the wing were unstalled in the power-off condition is estimated by

$C_{L_o} = C_{L_{\alpha_o}}\ 57.3 \sin(\alpha - \alpha_o)$ (equation 9.2.1-e)

α deg	$(\alpha - \alpha_o)$ deg	$\sin(\alpha - \alpha_o)$	C_{L_o}
-20	0	0	0
-10	10	0.1736	1.442
0	20	0.3420	2.842
10	30	0.5000	4.154
20	40	0.6428	5.341

Solution:

$$C_L'' = C_{L_o}(1 - T_c'') + \frac{F}{T} T_c'' \frac{KS_p}{S} \sin(\theta + \alpha) \left[1 + 1.6(1 - T_c'')^{1/2}\right] \text{(equation 9.2.1-a)}$$

$$= C_{L_o}(1 - 0.9) + (0.96)(0.9)\frac{(4)(3.14)}{(10.96)} \sin(\theta + \alpha) \left[1 + 1.6(1 - 0.9)^{1/2}\right]$$

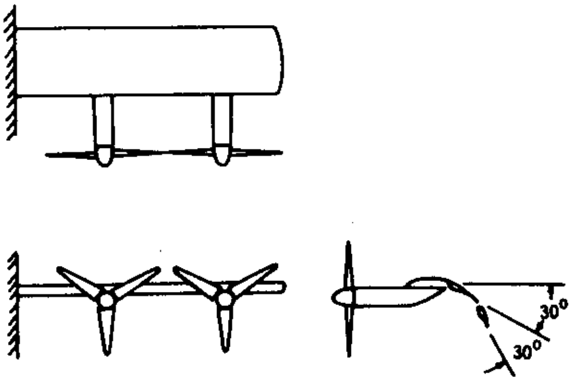
$$= 0.10\, C_{L_o} + 1.491 \sin(\theta + \alpha)$$

①	②	③	④	⑤	⑥	⑦
α deg	C_{L_o}	$(\theta + \alpha)$ deg	$\sin(\theta + \alpha)$ sin ③	$0.10\ C_{L_o}$ 0.10 ②	1.491 ④	C_L'' ⑤ + ⑥
-20	0	10.94	0.1898	0	0.2830	0.2830
-10	1.442	20.94	0.3574	0.1442	0.5329	0.6771
0	2.842	30.94	0.5141	0.2842	0.7665	1.0507
10	4.154	40.94	0.6553	0.4154	0.9771	1.3925
20	5.341	50.94	0.7764	0.5341	1.1576	1.6917

These results are compared with experimental data in table 9.2.1-A.

2. Deflected-Slipstream Configuration

Given: A propeller-wing-flap deflected-slipstream configuration of reference 2.



Wing Characteristics

$S = 10.96$ sq ft $\qquad A = 7.66 \qquad$ NACA 4415 airfoil section

$i_W = 0 \qquad c = 1.2$ ft (flaps retracted)

$c = 1.68$ ft (sliding flap and Fowler flap extended)

Flap Characteristics

Combination sliding and Fowler flap

$\frac{c_f}{c} = 0.566$ (sliding flap and Fowler flap extended; effective chord of sliding flap measured to flap knee)

$$\left.\begin{array}{l}\delta_{sliding} = 30^\circ \\ \delta_{Fowler} = 30^\circ\end{array}\right\} \delta = \delta_{sliding} + \delta_{Fowler} = 60^\circ$$

Propeller Characteristics

$K = 4$ (2 propellers per semispan, no overlap) $D = 2.0$ ft

$S_p = 3.14$ sq ft

Additional Characteristics

$T_c'' = 0.90 \qquad \delta_e = 7.4^\circ$

Compute:

Step 1. Determine the slipstream turning angle θ.

$$\frac{c_f}{D} = \left(\frac{c_f}{c}\right)\left(\frac{c}{D}\right) = (0.566)\left(\frac{1.68}{2.0}\right)$$

$$= 0.475$$

$\frac{\theta}{\delta} = 0.72$ (figure 9.2.1-18a at $\frac{c_f}{D} = 0.475$)

$\theta_f = \frac{\theta}{\delta}\,\delta = (0.72)(60)$ (equation 9.2.1-c)

$= 43.2^\circ$

Assuming the wing to be a large-chord flap

$$\frac{c}{D} = \frac{1.2}{2.0} = 0.60$$

$\frac{\theta}{\delta} = 0.803$ (figure 9.2.1-18a at $\frac{c}{D} = 0.60$)

$\Delta\theta = \frac{\theta}{\delta}\,\delta_e\ (0.803)(7.4)$ (equation 9.2.1-d)

$= 5.94^\circ$

$\theta = \theta_f + \Delta\theta = 43.2 + 5.94$ (equation 9.2.1-b)

$= 49.14^\circ$

Determine if the $\frac{\theta}{\delta}$ value for this wing-flap configuration is in the linear range.

$\theta_{max} = 53.5^\circ$ (upper curve of figure 9.2.1-18b at $\frac{c_f}{D} = 0.475$)

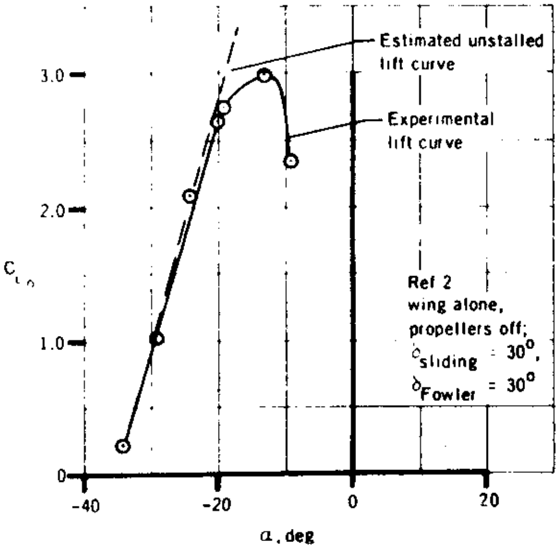
$\frac{\theta_f}{\theta_{max}} = \frac{43.2}{53.5} = 0.807$ which is within the range of linear variation of θ with δ as defined by the Datcom.

Step 2. Determine the thrust-recovery factor $\frac{F}{T}$.

$\frac{F}{T} = 0.90$ (figure 9.2.1-19)

Step 3. Determine the power-off lift coefficient C_{L_o}.

The experimental power-off lift curve is extrapolated to obtain



$\alpha_o = -35^o$

$C_{L_{\alpha_o}} = 0.180$ per deg

The lift curve that would exist if the wing were unstalled in the power-off condition is estimated by

$$C_{L_o} = C_{L_{\alpha_o}}\ 57.3 \sin(\alpha - \alpha_o) \qquad \text{(equation 9.2.1-e)}$$

α deg	$\alpha - \alpha_o$ deg	$\sin(\alpha - \alpha_o)$	C_{L_o}

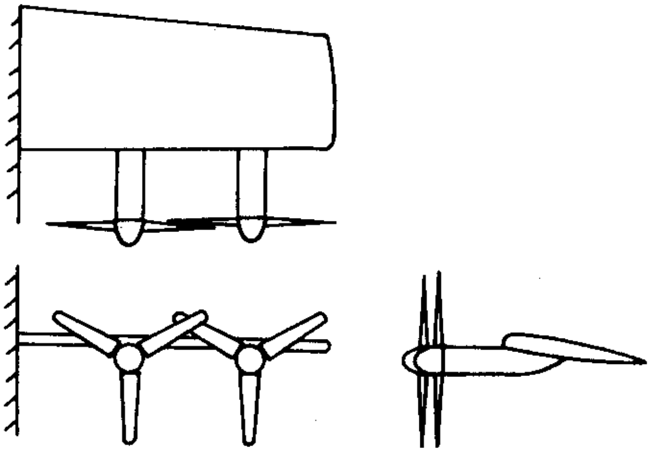
20	8.4492	69.14	0.9344	0.8449	1.3061	2.151

These results are compared with experimental data in table 9.2.1-A.

3. Tilt-Wing Configuration

Given: The propeller-wing configuration of reference 5.



Wing Characteristics

$S = 11.0$ sq ft $\quad A = 4.89 \quad i_W = 5^{\circ}$ NACA 4415 airfoil section

$c = 1.5$ ft

Propeller Characteristics

$K = 4$ (2 propellers per semispan, overlapped) $\quad D = 2.0$ ft

$S_p = 3.14$ sq ft

Additional Characteristics

$T_c'' = 0.69 \quad \delta_e = 12.4^{\circ}$

Compute:

Step 1. Determine the slipstream turning angle θ.

$\theta_f = 0$

$\frac{c}{D} = \frac{1.5}{2.0} = 0.75$

$\frac{\theta}{\delta} = 0.89$ (figure 9.2.1-18a at $\frac{c}{D} = 0.75$)

$\Delta\theta = \frac{\theta}{\delta}\delta_e = (0.89)(12.4)$ (equation 9.2.1-d)

$= 11.0^{\circ}$

$\theta = \theta_f + \Delta\theta$ (equation 9.2.1-b)

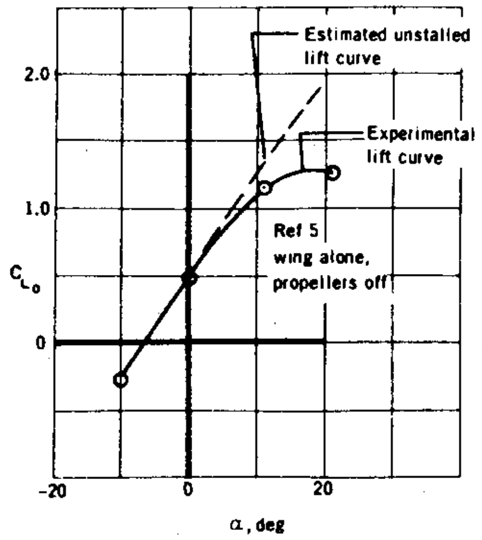
$= 11.0^{\circ}$

Step 2. Determine the thrust-recovery factor $\frac{F}{T}$.

$\frac{F}{T} = 1.0$ (figure 9.2.1-19)

Step 3. Determine the power-off lift coefficient C_{L_o}.

The experimental power-off lift curve is extrapolated to obtain



$\alpha_o = -6.5^\circ$

$C_{L_{\alpha_o}} = 0.075$ per deg

The lift curve that would exist if the wing were unstalled in the power-off condition is estimated by

$C_{L_o} = C_{L_{\alpha_o}}\ 57.3 \sin(\alpha - \alpha_o)$ (equation 9.2.1-

α deg	$(\alpha - \alpha_o)$ deg	$\sin(\alpha - \alpha_o)$	C_{L_o}

9.2.3 PROPELLER-WING-FLAP DRAG VARIATION WITH POWER AND ANGLE OF ATTACK

This Section presents a method for estimating the drag force of propeller-wing-flap configurations at combined forward speed and power-on conditions. The method is applicable only in the unstalled region of flight. The discussion in Section 9.2.1 is directly applicable to this Section, and the reader is referred to that discussion for a general description of the fundamental phenomena.

DATCOM METHOD

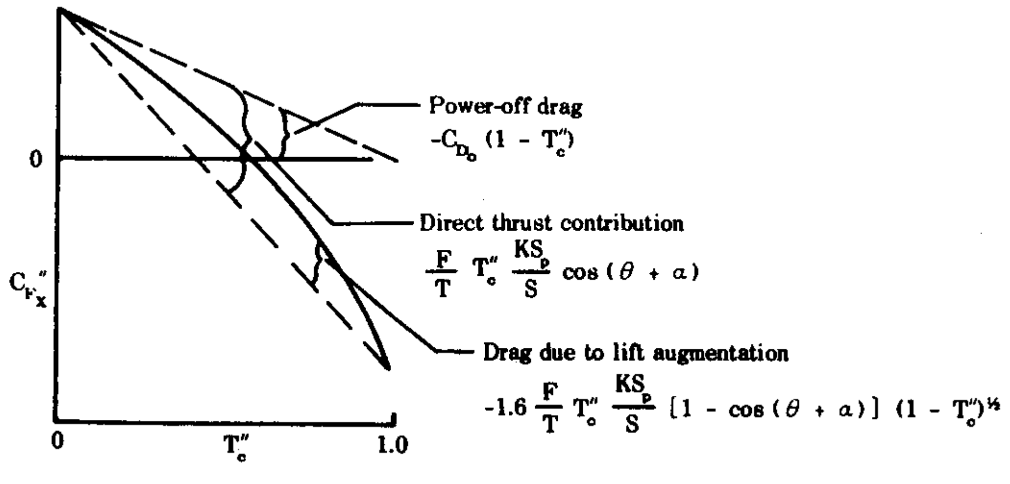
The negative drag force of a propeller-wing-flap configuration at combined forward speed and power-on conditions is given in reference 1 as

$$C_{F_X}'' = -C_{D_O}\,(1 - T_c'') + \frac{F}{T}\,T_c''\,\frac{KS_p}{S}\cos(\theta + \alpha)$$

$$-1.6\,\frac{F}{T}\,T_c''\,\frac{KS_p}{S}\left|1 - \cos(\theta + \alpha)\right|\,(1 - T_c'')^{1/2} \qquad 9.2.3\text{-a}$$

where all the parameters are defined in the general notation list of Section 9.2. The coefficients, except for C_{D_O}, are based on the dynamic pressure in the propeller slipstream, and the positive direction of forces and angles is shown in Figure 9.2-6.

The first term of equation 9.2.3-a represents the power-off drag contribution, the second term represents the component of thrust opposing the drag, and the third term represents the drag resulting from the lift augmentation due to the propeller slipstream. The significance of these terms is illustrated in sketch (a).



SKETCH (a)

The procedure to be followed in evaluating equation 9.2.3-a is outlined in the following steps.

Step 1. Determine the slipstream turning angle θ as in Step 1 of the method outline of Section 9.2.1.

In using this procedure to determine the slipstream turning angle it is necessary that the value be obtained over the linear part of the curve of variation of turning angle with flap deflection. The range of linear variation is defined in Step 1 of the method outline of Section 9.2.1.

Step 2. Determine the thrust-recovery factor $\frac{F}{T}$ as in Step 2 of the method outline of Section 9.2.1.

Step 3. Determine the power-off drag coefficient C_{D_o}.

A wing which is stalled in the power-off condition would frequently be unstalled at some moderate to high propeller thrust coefficient. In order to estimate the power-on data in this region, it is necessary to use the drag values that would exist if the wing were unstalled in the power-off condition. Where possible, experimental power-off data should be used for this purpose. Under these conditions the power-off drag coefficient can be estimated by

$$C_{D_o} = C_{D_f} + \frac{{C_{L_o}}^2}{\pi A e} \qquad 9.2.3\text{-b}$$

where

C_{D_f} is the power-off zero-lift drag coefficient. (For the purpose of the Datcom this coefficient is taken as the minimum experimental power-off drag coefficient in order to simplify the definition of the drag polar.)

C_{L_o} is the power-off lift coefficient obtained as in Step 3 of the method outline of Section 9.2.1

e is the span efficiency factor for the configuration. For the purpose of the Datcom $e = 0.85$.

If power-off data for the given configuration are not available or if power-off test data do not exhibit any region of unstalled flow, the following procedure should be used:

(a) Determine the power-off lift variation and α_o as in Step 3 of the method outline of Section 9.2.1.

(b) Determine the power-off zero-lift drag coefficient for the unflapped wing from Section 4.1.5.1.

(c) Determine the zero-lift drag increment due to flap deflection from Section 6.1.7.

then

$$C_{D_f} = C_{D_f(4.1.5.1)} + (\Delta C_D)_{(6.1.7)} \qquad 9.2.3\text{-c}$$

(d) The power-off drag coefficient of the flapped wing at angle of attack is then obtained from equation 9.2.3-b.

Step 4. The propeller thrust coefficient T_c'' will usually be specified; however, if necessary this parameter can be estimated using the method of Section 9.1.1. $\left(\text{Note that } T_{c_{9.2.1}} = T_{c_{9.1.1}} \frac{S_p}{S}, \text{ and } T_c'' = \frac{T_{c_{9.1.1}}}{T_{c_{9.1.1}} + K}.\right)$

Step 5. The drag force coefficient is then obtained from equation 9.2.3-a.

The sample problems illustrate the use of the Datcom method in estimating the horizontal-force coefficients of both deflected-slipstream and tilt-wing configurations.

Comparison of experimental data, in the unstalled flight regime, with calculations made using the Datcom method is presented for deflected-slipstream and tilt-wing configurations in Table 9.2.3-A.

Sample Problems

1. Deflected-Slipstream Configuration

Given: A propeller-wing-flap deflected-slipstream configuration of reference 2. This is the same configuration as that of sample problem 1 of Section 9.2.1. The characteristics are repeated below.

Wing Characteristics

$S = 10.96$ sq ft $A = 7.66$ NACA 4415 airfoil section

$i_W = 0$ $c = 1.2$ ft (flap retracted) $c = 1.68$ ft (Fowler flap extended)

Flap Characteristics

Fowler flap $\frac{c_f}{c} = 0.286$ (flap extended) $\delta = 50^\circ$

Propeller Characteristics

$K = 4$ (2 propellers per semispan, no overlap) $D = 2.0$ ft

$S_p = 3.14$ sq ft

Additional Characteristics

$T_c'' = 0.90$ $\delta_e = 7.4^\circ$

Compute:

Step 1. Determine the slipstream turning angle θ.

$\theta = 30.94^\circ$ (sample problem 1, Section 9.2.1)

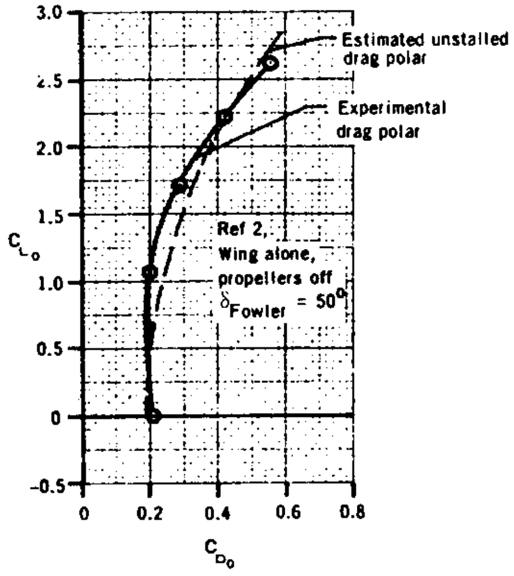
Also note that the variation of θ with δ for this wing-flap configuration was shown to be within the range of linear variation as defined by the Datcom.

Step 2. Determine the thrust-recovery factor $\frac{F}{T}$.

$\frac{F}{T} = 0.96$ (sample problem 1, Section 9.2.1)

Step 3. Determine the power-off drag coefficient C_{D_o}.

The power-off drag coefficient is obtained using the experimental zero-lift drag coefficient, and the power-off lift coefficient at angle of attack as determined in sample problem 1 of Section 9.2.1.



$C_{D_f} = 0.19$ (minimum experimental power-off drag coefficient)

The drag polar that would exist if the wing were unstalled in the power-off condition is estimated by

$$C_{D_o} = C_{D_f} + \frac{{C_{L_o}}^2}{\pi A e} \quad \text{(equation 9.2.3-b)}$$

α deg	C_{L_o} Problem 1 9.2.1	$\frac{{C_{L_o}}^2}{\pi Ae}$	C_{D_o}

10	1.0336	40.94	0.7555	0.1034	0.7479	0.1225	0.5220
20	1.5846	50.94	0.6302	0.1585	0.6239	0.1853	0.2801

These results are compared with experimental data in table 9.2.3-A.

2. Deflected-Slipstream Configuration

Given: A propeller-wing-flap deflected-slipstream configuration of reference 2. This is the same configuration as that of sample problem 2 of Section 9.2.1. The characteristics are repeated below.

Wing Characteristics

$S = 10.96$ sq ft $\quad A = 7.66 \quad$ NACA 4415 airfoil section

$i_W = 0 \quad c = 1.2$ ft (flaps retracted) $\quad c = 1.68$ ft (sliding flap and Fowler flap extended)

Flap Characteristics

$\frac{c_f}{c} = 0.566$ (sliding flap and Fowler flap extended; effective chord of sliding flap measured to flap knee)

$$\left.\begin{array}{l}\delta_{\text{sliding}} = 30^\circ \\ \delta_{\text{Fowler}} = 30^\circ\end{array}\right\} \delta = \delta_{\text{sliding}} + \delta_{\text{Fowler}} = 60^\circ$$

Propeller Characteristics

$K = 4$ (2 propellers per semispan, no overlap) $\quad D = 2.0$ ft

$S_p = 3.14$ sq ft

Additional Characteristics

$T_c'' = 0.90 \quad \delta_e = 7.4^\circ$

Compute:

Step 1. Determine the slipstream turning angle θ.

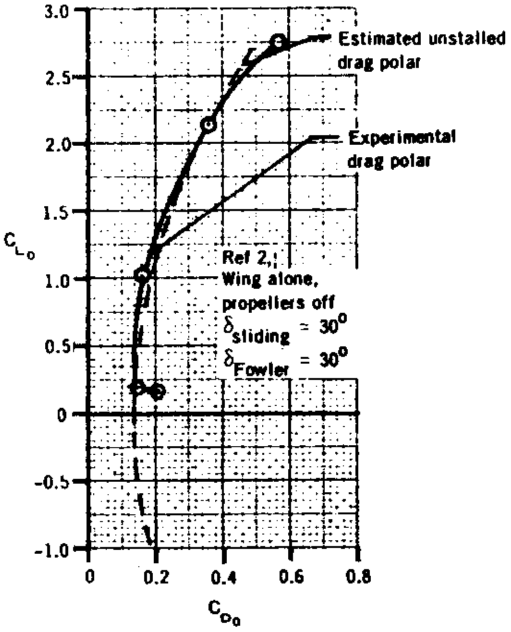
$\theta = 49.14^\circ$ (sample problem 2, Section 9.2.1) Also note that the variation of θ with δ for this wing-flap configuration was shown to be within the range of linear variation as defined by the Datcom.

Step 2. Determine the thrust-recovery factor $\frac{F}{T}$.

$\frac{F}{T} = 0.90$ (sample problem 2, Section 9.2.1)

Step 3. Determine the power-off drag coefficient C_{D_o}.

The power-off drag coefficient is obtained using the experimental zero-lift drag coefficient, and the power-off lift coefficient at angle of attack determined in sample problem 2 of Section 9.2.1.



$C_{D_f} = 0.14$ (minimum experimental power-off drag coefficient)

The drag polar that would exist if the wing were unstalled in the power-off condition is estimated by

$$C_{D_o} = C_{D_f} + \frac{{C_{L_o}}^2}{\pi A e} \quad \text{(equation 9.2.3-b)}$$

α deg	C_{L_o} Problem 2 9.2.1	$\frac{{C_{L_o}}^2}{\pi Ae}$	C_{D_o}

3. Tilt-Wing Configuration

Given: The propeller-wing configuration of reference 5. This is the same configuration as that of sample problem 3 of Section 9.2.1. The characteristics are repeated below.

Wing Characteristics

$S = 11.0$ sq ft $\qquad A = 4.89 \qquad i_W = 5^\circ \qquad$ NACA 4415 airfoil section

$c = 1.5$ ft

Propeller Characteristics

$K = 4$ (2 propellers per semispan, overlapped) $\quad D = 2.0$ ft

$S_p = 3.14$ sq ft

Additional Characteristics

$T_c'' = 0.69 \qquad \delta_e = 12.4^\circ$

Compute:

Step 1. Determine the slipstream turning angle θ.

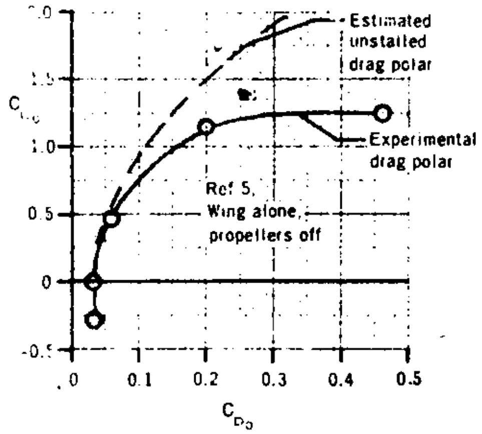
$\theta = 11.0^\circ$ (sample problem 3, Section 9.2.1)

Step 2. Determine the thrust-recovery factor $\frac{F}{T}$.

$\frac{F}{T} = 1.0$ (sample problem 3, Section 9.2.1)

Step 3. Determine the power-off drag coefficient C_{D_o}

The power-off drag coefficient is obtained using the experimental zero-lift drag coefficient, and the power-off lift coefficient at angle of attack determined in sample problem 3 of Section 9.2.1.



$C_{D_f} = 0.035$

The drag polar that would exist if the wing were unstalled in the power-off condition is estimated by

$$C_{D_o} = C_{D_f} + \frac{{C_{L_o}}^2}{\pi A e} \quad \text{(equation 9.2.3-b)}$$

9.3 DUCTED-PROPELLER CHARACTERISTICS

The estimation of ducted-propeller aerodynamics can be approached in three phases, each representing a VTOL aircraft flight regime. These are static operation (hovering), axial flow (approximately zero duct angle of attack as in cruise or vertical climb), and nonaxial flow (high duct angles of attack as in transition). The most important and most difficult problem is the prediction of the aerodynamic characteristics in the presence of strong power effects at high angles of attack and low speeds during transition.

The methods presented in this section are for predicting forces and moments on isolated ducted propellers as functions of power and angle of attack. The static and axial-flow regimes are trivial, and no attempt is made to deal with the characteristics in these regimes. It is virtually impossible to present quantitative information on the effects of the various geometric and aerodynamic variables involved because of the complexity of the problem and the general lack of appropriate data. However, a qualitative discussion of the ducted-propeller problem is given with primary emphasis on the nonaxial flow regime.

A ducted propeller consists of a propeller enclosed in an axially symmetric duct as shown in figure 9.3-12. The purpose of the duct is to increase the thrust-generating capability of the entire unit in the static and low subsonic speed regimes for a given propeller diameter and power input. If the chordwise cross section of the duct is reasonably faired, the unit can function as a ring wing as well as a thrusting propeller.

Differing from flying platforms or "flying jeeps," ducted-propeller units are typically mounted on the tips of low-aspect-ratio wings with the capability of rotating from 0 to 90 degrees. Since much of the ducted-propeller work has been the application to particular vehicle designs, the emphasis has been on propeller design and development of auxiliary devices to augment thrust and to provide control moments. This work is thus of little interest here because the lift and pitching moments are not affected significantly. The development of various auxiliary devices is reported in reference 84, and additional information pertaining to experimental investigations is given in table 9.3-A.

The duct complicates the problem of predicting the aerodynamic characteristics because of the strong mutual interference effects and the increased number of geometric variables. A preliminary list of geometric variables includes duct aspect ratio, duct section parameters (thickness ratio, camber, leading-edge radius, etc.), diffuser angle, propeller activity factor, propeller pitch setting, propeller solidity, propeller section parameters (twist, camber, taper, thickness, etc.), blade tip clearance, center-body location relative to the duct, center-body shape, ratio of hub diameter to propeller diameter, and propeller location within the duct. Aside from this seemingly endless list of geometric variables, there are the aerodynamic variables of angle of attack, Reynolds number, advance ratio, and Mach number.

The ducted propeller in the nonaxial flow regime has received very little theoretical attention in comparison to that given to the static and axial-flow regimes. The theoretical work available in the literature is generally classified under one of three general categories of analysis: (1) method of singularities, (2) momentum considerations, and (3) methods which seek to avoid the mathematical complexities of the method of singularities and yet yield more detailed results than simple momentum theory. The method of singularities is relatively complex, and almost all solutions in the literature are restricted to special classes of duct profiles. The method involves replacing the annular airfoil by a vortex distribution on its camber line, determining the axial and radial velocity components induced by this vortex distribution, and relating these velocity components to the shape of the airfoil by satisfying the potential flow streamline condition. Two approaches to the problem can be defined: (1) given the vortex distribution, find the corresponding shape and determine its aerodynamic characteristics, and (2) given the shape, find the corresponding vortex distribution, from which the aerodynamic characteristics can be determined. In either case, an iteration process is required if other than a first approximation is desired. The effects of geometric parameters and propellers are induced by the use of additional distributed singularities. The theoretical basis on which the method of singularities rests is developed and discussed in reference 57.

An approximate theory for nonaxial flow, based on the method of singularities, is developed by Burggraf in reference 1. Burggraf represents the ducted propeller as a short, thin, cylindrical duct with a uniformly loaded actuator disk across its exit plane. Each section of the duct is treated as a thin two-dimensional airfoil, and solutions are obtained by means of conformal transformations. An analysis with less restricted geometry has been made by Kriebel and summarized in reference 55. Kriebel treats the duct as a thin cylinder (but not necessarily short) and represents the propeller as a uniformly loaded actuator disk located at the duct inlet. The vorticity distribution bound to the duct and trailing from it is found in terms of a Fourier series by the method of singularities. The results are obtained by solving for the coefficients of the Fourier series representing the duct-bound vorticity distribution. Both Burggraf and Kriebel include the nonaxial flow case by assuming the vorticity shed by both the actuator disk and the duct to be concentrated on a circular cylinder which extends axially downstream, even at angles of attack. Because of this assumption, the exit velocity must be large relative to the cross-flow component. of the free-stream velocity, i.e.,

$$V_e >> V_\infty \sin \alpha_D ,$$

a restriction which requires high actuator disk loadings at high angles of attack.

Momentum theory in itself is not sufficient to predict the performance of a ducted propeller, since the relationships between thrust and power are in terms of the area and velocity of the final wake. At the present time, there appears to be no available way of relating wake characteristics to duct design without using the method of singularities. To avoid this difficulty some assumption must be made which relates the duct exit characteristics to the final wake. The most common assumption, forming what is generally termed "simple momentum theory," is that the final wake area is equal to the duct exit area. This implies that the exit velocity profile is uniform and the static pressure at the exit is equal to that at infinity. The nonaxial flow case is generally based on the additional assumption that the internal mass flow exits parallel to the duct axis, an assumption which is valid only for low duct aspect ratios and high exit-velocity ratios. Examples of simple momentum theory as applied to nonaxial flow are given in references 85 and 58.

Moser and Livingston, in reference 70, develop semiempirical expressions for the aerodynamic characteristics of ducted propellers in nonaxial flow by adapting blade element theory and modifications to it to take some account of duct influence. This method is shown to be reasonable for analyzing ducted-propeller characteristics where the deflection of the airstream is relatively small.

Minassian, in reference 65, treats the ducted propeller in nonaxial flow as a ring wing. He assumes that the propeller causes the internal pressures on the duct to cancel one another and then applies two-dimensional airfoil characteristics to predict normal-force variation with angle of attack. This work is restricted to rough approximations at low angles of attack and high advance ratios.

Wind-tunnel tests cover a wide variety of ducted propellers in the nonaxial flow regime; however, the data are often of questionable accuracy because of wall-interference effects and data accuracy limitations at the tunnel speeds required to simulate low-speed flight. Testing small models in an effort to avoid wall-interference effects has not proved satisfactory because of the errors associated with low Reynolds numbers and balance-system sensitivity. The uncertainties of wind-tunnel test data, coupled with the geometric and aerodynamic variables involved, preclude generalization and verification of any valid prediction methods. Although a large number of experimental investigations have been conducted, it is still difficult to draw any general conclusions pertaining to the effects of geometric or aerodynamic variations. However, the results that are available can serve at least to give a practical orientation to some aspects of the ducted propeller problem. Accordingly, a qualitative discussion of the effects of a number of the important variables is given.

Duct Leading-Edge Radius

The duct leading-edge radius is critical in that it must be large enough to prevent inlet flow separation at high power and/or angle of attack and yet not so large as to produce an excessive drag penalty in cruise flight. Leading-edge lip stall reduces lift and pitching moment and increases the power required.

Diffuser

A properly designed diffuser increases the diameter of the fully developed stream tube, thereby increasing the static thrust and efficiency of a given ducted propeller. Tests of two unpowered ducts (reference 36) in nonaxial flow indicate that diffusion of the duct afterbody results in an appreciable increase in lift-curve slope and maximum-lift stall angle of attack. Reference 36 also indicates that diffusion causes the center of pressure to move forward. These effects can be attributed to the increased internal mass flow through the duct resulting from increased positive circulation.

Although substantial diffusion may be beneficial in the static flow regime, it can lead to internal flow separation during essentially axial flow with an attendant drag increase.

Exit Stators

In addition to providing a structural tie between the center body and the duct, exit stators, because of twist and camber, also serve as guide vanes to eliminate the slipstream rotation resulting from the high thrust loading of the ducted propeller. This flow straightening converts the rotational kinetic energy to pressure and increased axial velocity. If flow straightening is not provided, the propeller efficiency is severely reduced.

Propeller Twist

The effect of propeller twist on static performance has been a source of controversy. The results reported in references 12 and 64 indicate that a relatively flat, untwisted blade is best for static and low-speed operation, because of the better match with the theoretical ring vortex circulation about the duct, resulting in gains in static efficiency. However, these reports make no statement regarding blade pitch optimization, and it is difficult to distinguish between the effects of blade twist and those of blade pitch. On the other hand, the results reported in references 19 and 56, which did use blade pitch optimization, show no such corresponding improvement and indicate that blade twist is relatively unimportant. Moser and Livingston, in reference 70, also indicate that the effects of blade twist are relatively unimportant except at the highest collective pitch tested.

Propeller Tip Clearance

Ducted-propeller efficiency increases with decreasing tip clearance. Excessive tip clearance will aggravate a condition of flow reversal that occurs on the duct in the propeller plane even for small tip clearances. At moderate to high angles of attack, the flow reversal condition on the lower inside surface of the duct can cause premature inlet lip separation, resulting in reductions in both lift and pitching moment accompanied by increased power requirements.

Propeller Position

The effect of propeller position on ducted-propeller forces and moments in nonaxial flow is relatively undefined. Reference 19 indicates that at a given thrust level, moving the propeller forward reduces the lift and pitching-moment coefficients. However, data of reference 57 indicate that forward movement of the propeller plane increases the radial variation in duct velocity distribution (greater velocities near the duct), which would be expected to increase the pitching moments in nonaxial flow.

It is stated in reference 55 that analytical results indicate that in axial flow the pressure jump acting upon the internal duct surface downstream of the propeller plane is maximum when the propeller plane is located at the minimum duct internal cross-sectional area. For this location of the propeller in axial flow, the disk area and disk thrust are minimum for a given disk loading, and the duct-to-disk thrust ratio and the propulsive efficiency are maximum.

Exit-Velocity Ratio and Angle of Attack

The exit-velocity ratio and angle of attack determine the basic flow pattern for a given ducted propeller. As the duct angle of attack is increased beyond the unpowered stall angle, the exit-velocity ratio must be increased to prevent stalling of the duct lower leading edge. Because of the predominance of power effects as duct angle of attack is increased, the separation that occurs on the top aft portion of the duct usually has a minor effect on force and moment data.

Reynolds Number

Reynolds-number effects are of extreme importance in ducted-propeller design because of the low airspeed of operation and the short streamwise lengths of ducted-propeller elements. The separation that occurs on the lower inside surface of the duct leading edge at high angles of attack and low exit-velocity ratios is a low Reynolds-number characteristic. At low Reynolds number, laminar flow is followed by separation rather than by attached turbulent flow, resulting in substantial losses in both lift and pitching moment at a given power setting.

A comprehensive tabulation of pertinent ducted-propeller experimental data in the nonaxial flow regime is presented as table 9.3-A. This table provides a brief outline of the test data contained in each report and indicates the basic parametric changes. Similar tables pertaining to the static- and axial-flow regimes are given in reference 84. It should be recognized that the ducted propeller problem cannot be satisfactorily handled by treating isolated effects with all other variables fixed. The effect of a geometric or aerodynamic variation on the characteristics of a ducted propeller of different design will very likely be quite different from that indicated by the test results of available reports.

A general notation list is included in this section for all ducted propeller sections. Figures 9.3-12 and 9.3-13 illustrate the geometric data required by the methods of these sections. Figure 9.3-13 also illustrates the positive sense of forces, moments, and angles.

NOTATION

A_D	duct aspect ratio, $\frac{d_e}{c}$
c	duct chord, ft
C_{D_e}	external duct drag coefficient, $\frac{-F_{x_e}}{q_\infty S_D}$
C_{F_x}	duct negative-drag coefficient, $\frac{F_x}{q_\infty S_D}$

$C_{F_{x_e}}$	external duct negative-drag coefficient, $\frac{F_{x_e}}{q_\infty S_D}$
C_L	duct lift coefficient, $\frac{L}{q_\infty S_D}$
C_m	duct pitching-moment coefficient, $\frac{M}{q_\infty S_D c}$
d_{CB}	duct center-body diameter at the exit plane, ft
d_e	duct exit diameter, ft
d_p	propeller diameter, ft
F_x	duct negative-drag force, lb $\left(F_x = C_{F_x} q_\infty S_D\right)$
J	advance ratio, $\frac{V_\infty}{nd_p}$
L	duct lift force, lb $(L = C_L q_\infty S_D)$
M	duct pitching moment, ft-lb $(M = C_m q_\infty S_D c)$
m_i	duct internal mass flow, $\frac{\text{slugs}}{\text{sec}}$
N	ducted-propeller normal force, lb
n	propeller rotational speed, rps
q_∞	free-stream dynamic pressure, $\frac{\text{lb}}{\text{sq ft}}$
S_D	duct planform area, sq ft $(S_D = d_e c)$
T	ducted-propeller thrust, lb
T_i	total internal thrust, lb
T_{net}	total net thrust, lb $(T_{net} = T_i - C_{D_e} q_\infty S_D)$

V_e	duct exit velocity, $\frac{\text{ft}}{\text{sec}}$
V_i	velocity increment of internal mass flow due to power, $\frac{\text{ft}}{\text{sec}}$
V_{i_o}	internal mass-flow velocity with power off, $\frac{\text{ft}}{\text{sec}}$
V_∞	free-stream velocity, $\frac{\text{ft}}{\text{sec}}$
$\frac{V_e}{V_\infty}$	exit-velocity ratio
$\bar{x}$	chordwise distance from the reference center to the unstalled duct center of pressure, positive for the center of pressure ahead of the reference center, ft
x_{cp}	chordwise distance from the duct leading edge to the center of pressure of the unstalled duct, positive aft of the duct leading edge, ft
x_m	chordwise distance from the duct leading edge to the reference center, positive aft of the duct leading edge, ft
α_D	angle of attack between duct axis and free-stream direction, deg
δ_{i_f}	net turning angle of the internal flow including power effects, deg
δ_{i_o}	turning angle of the internal flow with power off, deg

2	80	–	–	–	–	–	–	–	–	–	–	–									REVIEW AND CONSTRUCTION OF COMPARATIVE PERFORMANCE CHARTS USING DATA FROM A MAJORITY OF THE REPORTS ON THE REFERENCE LIST. HOVERING, TRANSITION, AND CRUISE. 2-DIMENSIONAL WATER-FLOW STUDIES.
8	68	MA	1.575, 1.647, 1.714, 2.103	3,4	2.5	1.83, 9.26	–	–	–	–	~2	–	X	X	X	X	X		X	X	SINGLE SHROUDED PROPELLER TESTED IN UAC 18-FT OCTAGONAL TUNNEL FOR HOVER UP TO M = .2 AND IN 8-FT TUNNEL FOR CRUISE. BLADE PITCH 20° – 56°. DIFFUSION ANGLE NOT GIVEN. RPM MEASURED. EFFECTS OF DUCT EXIT AREA RATIO, LIP SHAPE, DUCT CHORD LENGTH, PROPELLER POSITION, DUCT EXTERNAL SHAPE, INLET-VANE ANGLES, EXIT-VANE ANGLES, AND PROPELLER PARAMETERS, SUCH AS PLANFORM DISTRIBUTION, NO. OF BLADES, AND TIP CLEARANCE. TESTS RUN THROUGH RANGE OF PROP POWER LOADINGS AND FREE-STREAM MACH NOS. EFFECT OF EACH PARAMETER SEPARATELY.
9	67	MA	1.575, 1.647, 1.714, 2.103	3,4	2.5	1.83, 9.26	–	–	–	1.876 → 1.08	–	–	X	X	X	X	X		X	X	SAME CONFIG AS ABOVE. 15° → 42° BLADE TWIST. DIFFUSION VARIED, UP TO 12° (HALF-ANGLE) POWER SURVEY. THRUST DATA ONLY. EFFECTS ON PERFORMANCE OF DUCT EXIT AREA, DUCT CHORD LENGTH, PROPELLER POSITION, SHROUD EXTERNAL SHAPE, INLET-VANE ANGLES, EXIT-VANE ANGLES, AND PROPELLER PARAMETERS, SUCH AS PLANFORM DISTRIBUTION, NO. OF BLADES, AND TIP CLEARANCE. PRESSURE AND VELOCITY DATA USED TO COMPUTE PROP THRUST AND POWER-LOADING DISTRIBUTION AND DUCT DRAG AND SLIPSTREAM CONTRACTION. PRESS DATA SHOW EFFECT OF BLADE ANGLE, MACH NO., AND TIP SPEED. MAX AND MIN DUCT EXIT VELOCITIES GIVEN FOR BASIC CONFIG AND ALSO TO SHOW EFF OF VARYING RPM, BLADE ANGLE, MACH NO., DUCT EXIT AREA, DUCT CHORD LENGTH, INLET VANES, TIP CLEARANCE, NO. OF BLADES, AND PROP PLANFORM.
10	62	–	–	3	2.5	–	–	–	–	–	–	–	X	X	X		X	X			A DUCTED PROPELLER WITH FORWARD AND AFT GUIDE VANES AND BLC TESTED IN UAC TUNNEL. HAMILTON STANDARD VARIABLE CAMBER PROPELLER. DIFFUSION VARIES → 11° (HALF-ANGLE) AND 30° WITH BLC. PROP EFF PLOTS. THRUST FOR DUCT, PROP, AND TOTAL. ADVANTAGES OF DUCTED PROPELLER, METHODS OF DETERMINING PERFORMANCE, AND TEST DATA VERIFYING PREDICTED PERFORMANCE. HOVER, CRUISE, AND TRANSITION.
13	65	MA	2.26	3	8	–	–	0, 90°	76.5	–	–	–	X	X		X	X				FULL-SCALE HALF-MODEL SIMULATION OF DUAL TANDEM DUCTED-PROP VTOL AIRCRAFT TESTED OVER SAND AND STONE TO TEST ENGINE PROTECTIVE DEVICES. ISOLATED DUCT ALSO TESTED. 19°, 22.5°, 26° BLADE PITCH. DIFFUSION ANGLE NOT GIVEN. GROUND EFFECT. STATIC PRESSURE. EFFECTS OF PROP BLADE ANGLE, DUCT HEIGHT, POWER, AND DISTANCE BETWEEN DUCTS. THRUST AND TORQUE SHOW EFFECT OF RPM ALSO. APPENDIX INCLUDES PROP BLADE STRESS STUDIES MADE IN KELLETT DOWNWASH TEST FACILITY SHOWING EFF OF GROUND AND ADJACENT COMPONENTS ON VIBRATORY STRESSES ON BLADES OF DUCTED PROP.
14	69	MA	1.90	3	1.017	–	–	60° → 80°	–	–	–	–	X								3 TILT-WING CONFIG. LONG STABILITY CHAR (HORIZ-FORCE, VERTICAL-FORCE, PITCHING, AND VELOCITY-STABILITY DERIVS.) COMPARED WITH QUAD-DUCTED PROP CONFIG AND 2 HELICOPTERS. RPM MEASURED. HOVER AND TRANSITION. EQ FOR DERIVS.
15	64	MA	1.77	4	1.146	–	–	0° → 90°	–	–	–	–	X								VTOL CONFIG WITH 4 TILTING DUCTED PROPELLERS IN TANDEM. LIFT, LONG FORCE, AND PITCHING MOMENTS. RPM MEASURED. DIFFUSION ANGLE NOT GIVEN. EFFECT OF DIFFERENTIAL THRUST AND DIFFERENTIAL INCIDENCE ON AERO STAB AND CONTROL CHAR IN TRANSITION. TUFT GRID PICTURES.
16	60	BM	2.88	2	1.5	–	–	−10° → 90°	–	–	–	–			X	X					A TILTING DUCTED PROP AND A FAN-IN-WING IN MIT 7-1/2- × 10-FT TUNNEL. INCREMENTS IN LIFT, DRAG, AND PITCHING MOMENT, AND POWER COEFFICIENT TABULATED FOR TILT ANGLES OF −10° TO 90°, A BLADE PITCH SETTING OF 20°, AND TUNNEL VELOCITY OF 0 TO 40 MPH. MAX MASS FLOW VARIES FROM .288 TO .887 SLUGS/SEC. NO DIFFUSION. RPM MEASURED. TRANSITION REGIME. DUCT INFLOW VELOCITIES AND INLET PRESS DISTRIB. TUFT STUDY.
18	57	MA	.333, .667, 1.0, 1.5, 3.0	0	–	–	–	−4° → 90°	–	–	–	.704 → 2.11					X	X			5 ANNULAR AIRFOILS OF EQUAL PROJECTED AREAS IN LANGLEY 8- × 8-FT TUNNEL. NO DIFFUSION. LOW-SPEED STATIC LONG STAB CHAR. MAX L/D. LIFT-CURVE SLOPES AND DRAG POLARS COMPARED WITH CALC VALUES. TUFT GRID TESTS.

*MA = Modified Airfoil; BM = Bellmouth; NBM = Notched Bellmouth; +D = Plus Diffuser; TWC = Thin Walled Cylinder

9.3.1 DUCTED-PROPELLER LIFT VARIATION WITH POWER AND ANGLE OF ATTACK

The primary purpose of enclosing a propeller in a duct is to increase the thrust-generating capability in the static and low subsonic speed regimes for a given propeller diameter and power input. Because of strong mutual interference effects, the ducted-propeller aerodynamic characteristics are vastly different from those of a free propeller and an annular airfoil. The forces and moments acting on a ducted propeller may be considered as arising from the propeller forces, the duct forces, and the mutual interference of the duct and propeller.

As a consequence of the input of mechanical energy to a propeller delivering positive thrust, there is a pressure rise at the propeller disk, which is subsequently transformed into kinetic energy in the slipstream. If the propeller is enclosed within a fairing, a further velocity increment is produced at the propeller, which must be superimposed on the propeller flow. If this velocity increment is positive, the mass flow and consequently the total thrust are increased. This increase in force acts on the duct, and its magnitude depends upon the velocity increment due to the duct and the propeller loading. In addition, the mutual interference of the duct and propeller and other bodies which may be present results in an induced circulation, which may either increase or decrease the internal mass flow.

The Datcom methods presented for estimating forces and moments on ducted-propeller configurations require knowledge of only the total internal axial thrust rather than the thrust due to the propeller and to the duct at angle of attack. However, the fundamental phenomenon of ducted-propeller aerodynamics may be clarified somewhat by an analysis of the division of loads between the duct and the propeller.

The results of an investigation of the division of the forces and moments between a duct and a propeller of a ducted propeller are reported in reference 6. The investigation covered an angle-of-attack range and an advance-ratio range typical of the transition of a tilt-duct VTOL aircraft.

Figures 9.3.1-10a and 9.3.1-10b, reproduced from reference 6, present a comparison of the normal force, thrust force, and pitching moment on the propeller with the total model forces and moments, for an unstalled and a stalled duct, respectively. The unstalled configuration is the basic symmetrical duct shape modified by the addition of leading-edge fairings. These results show that the normal force and pitching moment acting on the propeller and spinner are relatively small in comparison with the total normal force and pitching moment of either the stalled or unstalle unit and that the duct is the primary source of normal force and pitching moment.

Figure 9.3.1-12, reproduced from reference 6, presents the variation of propeller thrust relative to total thrust with angle of attack for both the unstalled and the stalled duct configurations. In hovering ($V/nd_p = 0$), the propeller carries approximately 40 percent of the total thrust. At the highest value of the advance ratio tested, the propeller carries approximately 70 percent of the total thrust when α is near 0^o. For the unstalled operation, the propeller thrust ratio generally decreases with increasing angle of attack at a constant advance ratio. Beyond the stall the propeller thrust ratio increases with increasing angle of attack at a constant advance ratio. The increase can be attributed to the reduction in duct thrust caused by the lip stall.

Unpowered conditions correspond to a duct exit-velocity ratio of approximately 1.0. The exact value depends on the circulation about the duct. Annular wing reports, such as reference 2, may be used to estimate the forces and moments on an unpowered ducted propeller at angle of attack.

For convenience, the methods presented in subsequent Sections provide wind-axis aerodynamic force coefficients: conventional lift and drag coefficients normal and parallel to the free stream. The aerodynamic force and moment coefficients are referred to free-stream dynamic pressure.

Ducted propeller forces and moments are compared with those predicted by the Datcom methods in this and the following Sections. The experimental data represent a wide variation of duct and propeller variables over angle-of-attack and advance-ratio ranges typical of the transition range of a tilting duct VTOL aircraft. Experimental axial-thrust values have been used in the Datcom method calculations. A comparison of some of the pertinent geometric and aerodynamic parameter variations of the test configurations can be made by referring to the reference list of this Section and the reference list and table 9.3-A of Section 9.3. The Datcom methods are based on modifications to simple momentum theory and do not account for the possible wide variation in design parameters.

The lift predicted by the Datcom method of this Section compares favorably with test results throughout the range of the investigation. On the other hand, the pitching moment and drag predicted by the Datcom methods of Sections 9.3.2 and 9.3.3, respectively, vary noticeably from experimental results.

The method presented in this Section for the estimation of the lift of a ducted propeller is expressed as the sum of the lift components resulting from the internal and external mass flows. The internal-mass-flow component is estimated on the basis of simple momentum theory with empirical flow-turning corrections as a function of the duct aspect ratio and the duct exit-velocity ratio. The external-mass-flow component is estimated on the basis of empirical modifications of the data of references 1 and 2.

DATCOM METHOD

The method presented for the estimation of ducted-propeller lift coefficient is expressed as the sum of the components resulting from the internal and external mass flows. This approach is summarized by

$$\begin{aligned} C_L &= \frac{L}{q_\infty \, S_D} = C_{L_i} + C_{L_e} \\ &= \frac{\pi A_D}{2}\left[1 - \left(\frac{d_{CB}}{d_e}\right)^2\right]\left(\frac{V_e}{V_\infty}\right)^2 \sin \delta_{i_f} + C_{L_e} \end{aligned} \qquad 9.3.1\text{-a}$$

where

C_{L_i} is the lift coefficient resulting from the internal mass flow

C_{L_e} is the lift coefficient resulting from the external mass flow. It is obtained from figure 9.3.1-13 as a function of duct aspect ratio and angle of attack. Figure 9.3.1-13 is based on empirical modifications of the data of references 1 and 2.

δ_{i_f} is the net turning angle of the internal flow including power effects.

The basic approach to the solution of equation 9.3.1-a is as follows:

1. Determine the turning angle of the internal flow neglecting the effects of power.
2. Determine the exit-velocity ratio V_e/V_∞.
3. Determine the net turning angle of the internal flow including power effects.
4. Evaluate the internal-flow lift contribution using the terms obtained in steps 2 and 3 above.

The results of reference 2 indicate that the lift-curve slope of annular wings is twice that of plane unswept wings of the same aspect ratio. Based on simple momentum theory, the usual small-angle approximation, and the assumption of no lip separation, the turning angle of the internal flow, neglecting power effects, is

$$\delta_{i_o} \approx \sin^{-1}\left(\frac{C_{L_\alpha}\alpha}{\pi A_D}\right) \qquad 9.3.1\text{-b}$$

The unpowered, internal-flow turning angle relative to duct angle of attack is presented in figure 9.3.1-14 as a function of duct aspect ratio. Figure 9.3.1-14 is based on the unstalled test data of reference 2 and equation 9.3.1-b.

Addition of power causes further turning of the internal flow. This turning occurs forward of the propeller plane because of the closed boundaries of the duct. The flow is assumed to pass through the duct normal to the propeller plane, and the total velocity increase imparted to the internal flow (V_i) is assumed to be the difference between the duct exit velocity and the free-stream velocity. This results in the following expression for the net turning angle of the internal flow, including power effects (see figure 9.3-11b).

$$\delta_{i_f} \approx \sin^{-1}\left[\frac{V_\infty \sin\delta_{i_o} + (V_e - V_\infty)\sin\alpha_D}{V_e}\right] \qquad 9.3.1\text{-c}$$

The total lift contribution of a ducted propeller is obtained from the procedure outlined in the following steps:

Step 1. Determine the turning angle of the internal flow, neglecting power effects, by

$$\delta_{i_o} = \alpha_D\left(\frac{\Delta\delta_{i_o}}{\Delta\alpha_D}\right) \qquad 9.3.1\text{-d}$$

where $\frac{\Delta\delta_{i_o}}{\Delta\alpha_D}$ is obtained from figure 9.3.1-14 as a function of duct aspect ratio.

Step 2. Determine the exit-velocity ratio $\frac{V_e}{V_\infty}$ using

$$\frac{V_e}{V_\infty} = \frac{1 + \sqrt{1 + \frac{2T_i}{q_\infty S_e}}}{2} \qquad 9.3.1\text{-e}$$

where

S_e is the flow area at the duct exit plane $= \frac{\pi d_e^2}{4}\left[1 - \left(\frac{d_{CB}}{d_e}\right)^2\right]$

T_i is the total internal axial thrust ($\alpha_D = 0$), obtained as the sum of the net axial thrust T_{net} and the external duct drag.

$$T_i = T_{net} + C_{D_e} q_\infty S_D \qquad 9.3.1\text{-f}$$

Estimation of the net axial thrust is a ducted-propeller performance problem and is consequently outside the scope of the Datcom. A propulsion engineer should be consulted for this parameter.

The external duct drag C_{D_e} is obtained from figure 9.3.3-4 at $\alpha_D = 0^o$, where $C_{D_e} = -C_{F_{x_e}}$

Step 3. Using equation 9.3.1-c, obtain δ_{i_f} with the δ_{i_o} and $\frac{V_e}{V_\infty}$ values from Steps 1 and 2 above.

Step 4. Determine the internal-mass-flow lift-coefficient contribution by

$$C_{L_i} = \frac{\pi A_D}{2}\left[1 - \left(\frac{d_{CB}}{d_e}\right)^2\right]\left(\frac{V_e}{V_\infty}\right)^2 \sin \delta_{i_f} \qquad 9.3.1\text{-g}$$

Step 5. Obtain the lift coefficient C_{L_e} from figure 9.3.1-13 as a function of the duct aspect ratio and angle of attack.

Step 6. The total lift coefficient is given by equation 9.3.1-a

$$C_L = C_{L_i} + C_{L_e}$$

A comparison of test data with ducted-propeller lift coefficients computed by this method is shown in Table 9.3.1-A.

Sample Problem

Given: The ducted propeller configuration of reference 1

$d_e = 4.525$ ft $\quad d_{CB} = 1.208$ ft $\quad c = 2.75$ ft $\quad S_D = 12.45$ sq ft

Additional Characteristics

$V_\infty = 93.5$ ft/sec $\quad \alpha_D = 30^\circ$ $\quad T_{net} = 635$ lb $\quad$ Sea level $\quad q_\infty = 10.4$ lb/sq ft

Compute:

Step 1. Determine the turning angle of the internal mass flow without power effects.

$$A_D = \frac{d_e}{c} = \frac{4.525}{2.75} = 1.645$$

$$\frac{\Delta\delta_{i_o}}{\Delta\alpha_D} = 0.830 \quad \text{(figure 9.3.1-14)}$$

$$\delta i_o = \alpha_D\left(\frac{\Delta\delta_{i_o}}{\Delta\alpha_D}\right) \quad \text{(equation 9.3.1-d)}$$

$$= (30)(0.830)$$

$$= 24.9 \text{ deg}$$

Step 2. Determine the exit-velocity ratio

$$C_{D_e} = -C_{F_{X_e}} = 0.022 \quad \text{(figure 9.3.3-4, at } \alpha_D = 0)$$

$$T_i = T_{net} + C_{D_e} q_\infty S_D \quad \text{(equation 9.3.1-f)}$$

$$= 635 + (0.022)(10.4)(12.45)$$

$$= 637.7 \text{ lb}$$

$$S_e = \frac{\pi d_e^2}{4}\left[1 - \left(\frac{d_{CB}}{d_e}\right)^2\right] = \frac{\pi(4.525)^2}{4}\left[1 - \left(\frac{1.208}{4.525}\right)^2\right]$$

$$= 16.10 \quad (0.9295)$$

$$= 14.97 \text{ sq ft}$$

$$\frac{V_e}{V_\infty} = \frac{1 + \sqrt{1 + \frac{2T_i}{q_\infty \quad S_e}}}{2} \quad \text{(equation 9.3.1-e)}$$

$$= \frac{1 + \sqrt{1 + (2)\frac{637.7}{(10.4)(14.97)}}}{2}$$

$$= \frac{1 + \sqrt{1 + 8.19}}{2}$$

$$\frac{V_e}{V_\infty} = 2.02$$

Step 3. Determine the net turning angle of the internal mass flow, including power effects.

$$\delta_{i_f} \approx \sin^{-1}\left[\frac{V_\infty \sin \delta_{i_o} + (V_e - V_\infty) \sin \alpha_D}{V_e}\right] \text{(equation 9.3.1-c)}$$

$$= \sin^{-1}\left[\frac{(93.5)(0.421) + (189 - 93.5)(0.50)}{189}\right]$$

$$= \sin^{-1} (0.4609)$$

$$= 27.45 \text{ deg}$$

Step 4. Determine the lift-coefficient contribution of the internal mass flow.

$$C_{L_i} = \frac{\pi A_D}{2}\left[1 - \left(\frac{d_{CB}}{d_e}\right)^2\right]\left(\frac{V_e}{V_\infty}\right)^2 \sin \delta_{i_f} \quad \text{(equation 9.3.1-g)}$$

$$= \frac{\pi(1.645)}{2} (0.9295)(2.02)^2(0.4604)$$

$$= 4.53$$

Step 5. Determine the lift-coefficient contribution of the external mass flow.

$$C_{L_e} = 0.69 \quad \text{(figure 9.3.1-13)}$$

Solution:

$$C_L = C_{L_i} + C_{L_e} \quad \text{(equation 9.3.1-a)}$$

$$= 4.53 + 0.69$$

$$= 5.22$$

This corresponds to an experimental value of 5.40 obtained from reference 1.

9.3.2 DUCTED-PROPELLER PITCHING-MOMENT VARIATION WITH POWER AND ANGLE OF ATTACK

This Section presents a method for estimating ducted-propeller pitching moments as functions of power and angle of attack. The basic discussion in Section 9.3.1 is directly applicable to this Section, and the reader is referred to that discussion for a general description of the fundamental phenomenon.

DATCOM METHOD

The method presented for estimating ducted-propeller pitching moments is based on ring vortex and simple momentum theories with empirical modifications.

The pitching moment consists of three component parts:

(1) A circulation-induced moment which in effect causes a shift in axial duct forces (essentially a shift in thrust axis.)
(2) A moment due to the lift component
(3) A moment due to the negative drag component

The circulation-induced moment is always positive (nose-up) and increases with increasing power. The last two components also increase in magnitude with power but may be positive or negative depending upon the location of the ducted-propeller center of pressure. This method assumes the center-of-pressure location to be independent of power and angle of attack and to be on the duct axis at the unstalled center-of-pressure location of the undiffused annular wings of reference 2.

The pitching-moment contribution of a ducted-propeller configuration, based on the duct planform area and duct chord and referred to an arbitrary moment center, is given by

$$C_m = \frac{\pi A_D}{2}\left(\frac{V_e}{V_\infty} - \cos\ \delta_{1_f}\right)\sin \alpha_D + \frac{\bar{x}}{c}\left(C_L \cos \alpha_D - C_{F_x} \sin \alpha_D\right) \qquad 9.3.2\text{-a}$$

where the first term on the right-hand side is the circulation-induced moment as derived by Sacks in reference 1, modified by the empirical relation for the net turning angle of the internal flow, discussed in Section 9.3.1. The last two terms are the components due to lift and drag.

$\frac{V_e}{V_\infty}$ is the exit-velocity ratio, obtained from equation 9.3.1-e

δ_{1_f} is the internal-flow turning angle, including the effects of power, obtained from equation 9.3.1-c

C_L is the total lift coefficient of the ducted propeller, obtained from Section 9.3.1

C_{F_x} is the total negative drag coefficient of the ducted propeller, obtained from Section 9.3.3

$\frac{\bar{x}}{c} = \left(\frac{x_m}{c} - \frac{x_{cp}}{c}\right)$, the chordwise distance, in duct chords, from the reference center to the unstalled duct center of pressure, positive for the center of pressure ahead of the reference center

$\frac{x_m}{c}$ is the chordwise distance, in duct chords, from the duct leading edge to the reference center, positive aft of the duct leading edge

$\frac{x_{cp}}{c}$ is the chordwise distance, in duct chords, from the duct leading edge to the center of pressure of the unstalled duct, positive aft of the duct leading edge. It is obtained as a function of duct aspect ratio from figure 9.3.2-6.

A comparison of test data with ducted propeller pitching-moment coefficients computed by this method is shown in table 9.3.2-A.

Because of the number of variables involved in the ducted propeller problem and the design parameters not considered in the Datcom method, the comparison between theory and experiment cannot be analyzed by examining the isolated effect of one variable. However, it is felt that one important factor pertaining to the test conditions of the available data, namely scale effect, should be considered before assessing the accuracy of this method. The data presented in reference 1 of table 9.3.2-A are the only available test results of a large-scale ducted propeller in the non-axial flow regime. Although experimental data on similar models of different scale are needed for the proper evaluation of the scale effect, it is felt that the low Reynolds numbers of small scale tests will appreciably affect the stalling characteristics of the duct. Therefore, comparison of calculated and large-scale experimental results of reference 1 in table 9.3.2-A is more indicative of the accuracy of the method than comparison with the other reference data.

Sample Problem

Given: Same ducted propeller configuration as sample problem of Section 9.3.1. Some of the characteristics are repeated below.

$d_e = 4.525$ ft $\quad d_{CB} = 1.208$ ft $\quad c = 2.75$ ft

$A_D = 1.645$ $\quad S_D = 12.45$ sq ft

Additional Characteristics

$V_\infty = 93.5$ ft/sec $\quad \alpha_D = 30^\circ$ $\quad$ Sea level

Moment reference center at 0.49c $\quad q_\infty = 10.4$ lb/sq ft

Compute:

$$\left.\begin{aligned} \frac{V_e}{V_\infty} &= 2.02 \\ \delta_{i_f} &= 27.45^\circ \\ C_L = C_{L_i} + C_{L_e} &= 5.22 \end{aligned}\right\} \text{(sample problem Section 9.3.1)}$$

$C_{F_x} = 3.455$ (sample problem Section 9.3.3)

$\frac{x_{cp}}{c} = 0.266$ (figure 9.3.2-6)

$$\frac{\bar{x}}{c} = \frac{x_m}{c} - \frac{x_{cp}}{c}$$

$$= (0.49 - 0.266)$$

$$= 0.224$$

Solution:

$$C_m = \frac{\pi A_D}{2}\left(\frac{V_e}{V_\infty} - \cos \delta_{i_f}\right) \sin \alpha_D + \frac{\bar{x}}{c}\left(C_L \cos \alpha_D - C_{F_x} \sin \alpha_D\right) \quad \text{(equation 9.3.2-a)}$$

$$= \frac{\pi(1.645)}{2} (2.02 - 0.8874)(0.50) + 0.224 \left| (5.22)(0.866) - (3.455)(0.50) \right|$$

$$= (2.58)(1.1326)(0.50) + 0.224\ (2.792)$$

$$= 2.085$$

This corresponds to an experimental value of 1.899 obtained from reference 1.

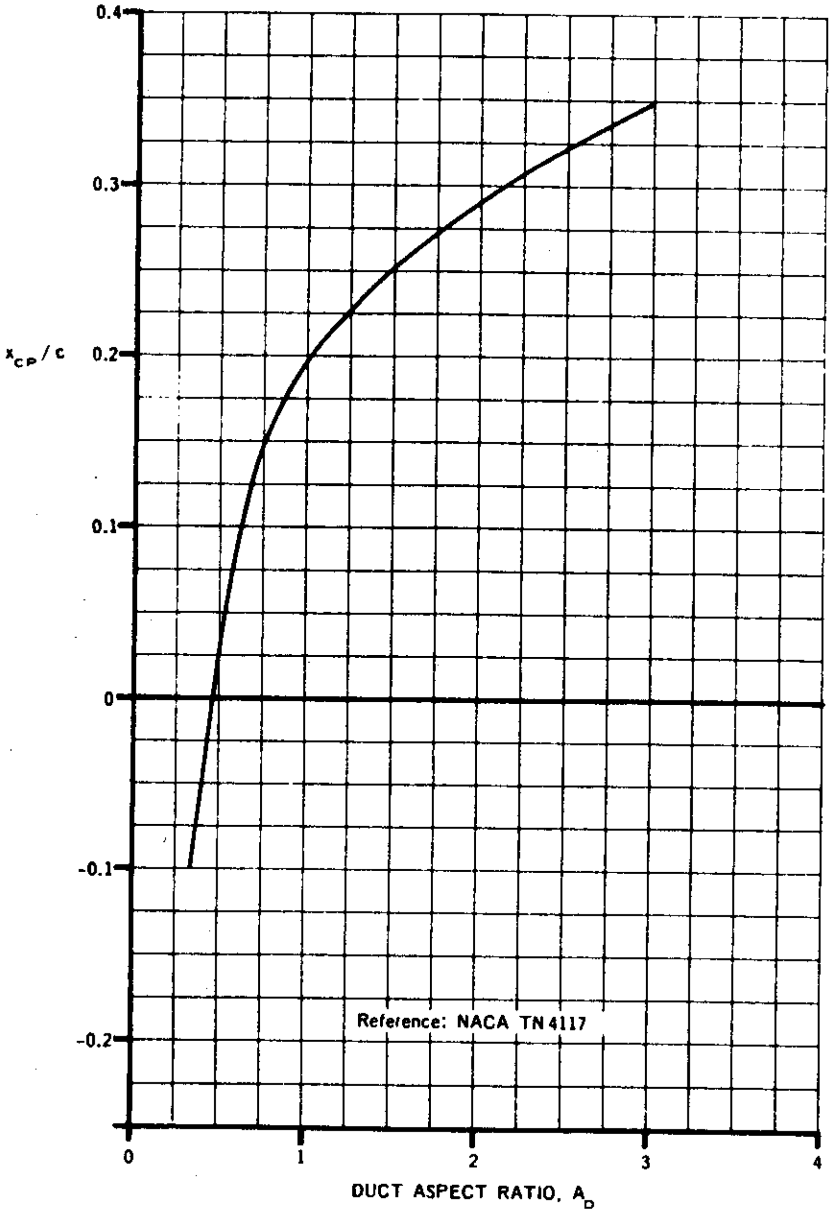

FIGURE 9.3.2-6 DUCT CENTER OF PRESSURE LOCATION

9.3.3 DUCTED-PROPELLER DRAG VARIATION WITH POWER AND ANGLE OF ATTACK

This Section presents a method for estimating ducted-propeller drag as a function of power and angle of attack. The basic discussion in Section 9.3.1 is directly applicable to this Section, and the reader is referred to that discussion for a general description of the fundamental phenomenon.

DATCOM METHOD

The method presented for estimating ducted-propeller drag is expressed as the sum of the components resulting from the internal and external mass flows. The theoretical basis of this method is the same as that of the Datcom lift-estimation method of Section 9.3.1.

The negative drag coefficient of a ducted propeller is given by

$$C_{F_x} = \frac{\pi A_D}{2}\left[1 - \left(\frac{d_{CB}}{d_e}\right)^2\right]\left[\left(\frac{V_e}{V_\infty}\right)^2 \cos\delta_{i_f} - \left(\frac{V_e}{V_\infty}\right)\right] + C_{F_{x_e}} \qquad \text{9.3.3-a}$$

where the first term on the right-hand side is due to internal flow and is estimated on the basis of simple momentum theory modified by the empirical relation for the net internal-flow turning angle, discussed in Section 9.3.1.

$\frac{V_e}{V_\infty}$ is the exit-velocity ratio, obtained from equation 9.3.1-e

δ_{i_f} is the net turning angle of the internal flow, obtained from equation 9.3.1-c

$C_{F_{x_e}}$ is the external negative drag coefficient, resulting from the external flow, obtained from figure 9.3.3-4 as a function of duct aspect ratio and angle of attack. Figure 9.3.3-4 is based on empirical modifications of the data of references 1 and 2.

A comparison of test data with ducted-propeller drag coefficients computed by this method is shown in table 9.3.3-A. The measurement of drag involves the difference between the components of the thrust force and the normal force and is inherently less accurate than the measurement of the lift force. At a tunnel velocity near that for steady level flight ($C_{F_x} = 0$), slight errors in drag measurement can result in test values with an opposite sign than that predicted by theory; and percent error becomes incalculable, although the actual magnitude of the difference may be less than that for lift. Consequently, a comparison of theory and experiment in this area may be misleading when presented in terms of percent error. Therefore, a summary of the results presented in table 9.3.3-A is presented as a weighted error.

Sample Problem

Given: Same ducted-propeller configuration as sample problem of Section 9.3.1. Some of the characteristics are repeated below.

$d_e = 4.525$ ft $d_{CB} = 1.208$ ft $c = 2.75$ ft

$A_D = 1.645$ $S_D = 12.45$ sq ft

Additional Characteristics

$V_\infty = 93.5$ ft/sec — Sea level

$\alpha_D = 30^\circ$ — $q_\infty = 10.4$ lb/sq ft

Compute:

$$\left.\begin{aligned} \frac{V_e}{V_\infty} &= 2.02 \\ \delta_{i_f} &= 27.45^\circ \end{aligned}\right\} \text{(sample problem Section 9.3.1)}$$

$$\left[1 - \left(\frac{d_{CB}}{d_e}\right)^2\right] = 0.9295$$

$$C_{F_{x_e}} = -0.395 \quad \text{(figure 9.3.3-4)}$$

Solution:

$$C_{F_x} = \frac{\pi A_D}{2}\left[1 - \left(\frac{d_{CB}}{d_e}\right)^2\right]\left[\left(\frac{V_e}{V_\infty}\right)^2 \cos\delta_{i_f} - \left(\frac{V_e}{V_\infty}\right)\right] + C_{F_{x_e}} \quad \text{(equation 9.3.3-a)}$$

$$= \frac{\pi(1.645)}{2}(0.9295)\left[(2.02)^2(0.8874) - (2.02)\right] + (-0.395)$$

$$= (2.41)(1.60) - 0.395$$

$$= (3.455)$$

This corresponds to an experimental value of 3.785 obtained from reference 1.
